hemoglobin results. This forms the basis of blood oxygen level-dependent (BOLD) imaging, the most commonly used functional (f) MRI method. fMRI is likely to take over from emission CT as the method of choice for brain activity imaging. It does not involve any radiation exposure and can, therefore, be repeated many times. It also has a greater spatial (2–5 mm) and time resolution (about 100 ms) than PET or SPECT.

Magnetic Resonance Spectroscopy

Local magnetic field strengths vary relative to their molecular, i.e., chemical, context. This results in slight changes of resonance frequency that can be measured with magnetic resonance spectroscopy (MRS). MRS thus allows the chemical imaging of certain biologically important molecules. Nuclei commonly used in MRS are ^1H , which, after suppression of the water signal, yields measures of compounds such as glutamate, lactate, *N*-acetyl-aspartate, choline, and creatinine, and ^{31}P , which gives estimates of the markers of energy metabolism ATP/ADP and of membrane metabolism, phosphomono- or phosphodiesteres, and phosphocreatinine. The volumes studied with MRS lie in the range of several cubic centimeters.

Structural and Functional Brain Changes Associated with Stress-Related States

A number of psychiatric and medical syndromes have a *prima facie* or conceptual association with stress. The obvious connection is with posttraumatic stress disorder (PTSD), but some affective disorders, such as major depressive disorder (MDD) and bipolar affective disorder (BAD), present with aspects of the classical stress response; medically caused hypercortisolism, such as Cushing's syndrome and aging in some patients, may be relevant in this context.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD), as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, of the American Psychiatric Association, is an anxiety disorder that arises and persists in the aftermath of an emotionally traumatic event. Specifically, patients with PTSD (1) re-experience phenomena that may occur spontaneously or in response to reminders of the traumatic event (i.e., flashbacks), (2) avoid reminders of the event, and (3) exhibit generalized hyperarousal (i.e. exaggerated startle response). One of the core symptoms of PTSD in trauma survivors is a disturbance in memory function. Traumatic events such as acts of terrorism, war, and sexual or physical abuse can trigger PTSD that can persist for months or years following the actual event.

Kolb proposed a neuropsychological hypothesis of PTSD in the late 1980s, which implies that stress-related neuroanatomical changes might underlie symptom formation in PTSD. Numerous empirical studies have provided support for the notion that trauma can trigger neurochemical and neuroanatomical changes leading to emotional dysregulation and exaggerated stress reactivity in susceptible individuals. Such research has implicated the hippocampus, amygdala, anterior cingulate, Broca's area, and medial prefrontal cortex.

Structural imaging studies Adults with PTSD related to combat exposure or childhood physical or sexual abuse have smaller hippocampi compared with healthy volunteers. Findings have been generally consistent. However, results are equivocal as to whether the reduction in hippocampal volume occurs predominantly in the left or the right hippocampus. Suggestions as to why hippocampal volume is reduced in this diagnostic group are that diminished hippocampal size may be either a consequence of exposure to trauma or a risk factor for the development of psychiatric complications such as PTSD.

It has long been known that the hippocampus is involved in memory function and learning; the hippocampus together with the amygdala, orbitofrontal cortex, and anterior cingulate are thought to be part of a circuit involved in the processing of information and the creation of emotional and declarative memories. Core symptoms of PTSD are disturbances of memory function and deficits in attention, so research has aimed to examine the possible relationship between reduced hippocampal volume and memory and attention deficits in this diagnostic group, so far unsuccessfully.

Pitman and colleagues hypothesized in the early 2000s that pre-existing diminished whole brain and hippocampal volume may increase the risk of exposure to traumatic events capable of causing PTSD. Because the hippocampus is involved in declarative memory, those with smaller hippocampi from birth or due to adverse development during childhood may be less able to learn from experience and therefore avoid dangerous situations. Exposure to traumatic events may be increased, with the consequent risk of developing PTSD. Another possibility is that a pre-existing anatomical abnormality may increase the individual's vulnerability to developing PTSD after exposure to a traumatic event. In particular, there is evidence that the hippocampus is involved in the extinction of conditioned responses; individuals with brain abnormalities such as reduced hippocampal volume may, therefore, be poorer extinguishers of conditioned responses and thereby be more likely to

develop PTSD. This vulnerability hypothesis (i.e., primary hippocampal abnormalities result in increased risk of PTSD) needs to be supported by expensive and difficult-to-conduct prospective imaging studies. More economically, examining PTSD-unaffected twins of PTSD victims can tease apart congenital, in lieu of pre-existing, from secondary hippocampal abnormalities. First evidence from this approach is now emerging.

Functional imaging studies The majority of functional brain imaging studies have employed a symptom provocation paradigm, to track the brain equivalents of PTSD and also because measuring brain function at rest makes it difficult to control the variability of possible resting mental states. Symptom provocation paradigms in combination with functional neuroimaging provide an important tool for visualizing neuroanatomical correlates of psychiatric symptoms. Liberzon and colleagues investigated the neurobiological role of limbic brain regions in PTSD, such as amygdala, hippocampal formation, hypothalamus, thalamus, and nearby paralimbic cortex, such as the anterior cingulate cortex, orbitofrontal cortex insula, and temporal poles. Fourteen PTSD patients and two control groups (11 combat controls and 14 healthy volunteers) were scanned with SPECT to measure regional cerebral perfusion in two settings: immediately after exposure to a provocative stimulus and after a nonprovocative control stimulus. During exposure to traumatic stimuli, the researchers noted that the PTSD patients demonstrated the characteristic exaggerated psychological and psychophysiological responses, similar to those documented in previous literature. PTSD patients had increased rCBF in relevant areas of the limbic brain in the vicinity of the left amygdala/nucleus accumbens. No comparable activation was found in either control group. Given the role that these neuroanatomical structures play in the regulation of mental processes in PTSD, the findings from this study support and extend the existing evidence of limbic system and extended amygdala involvement in PTSD symptoms.

Functional MRI studies have employed the masked-faces paradigm to assess automatic amygdala responsivity to general threat-related stimuli in PTSD. Findings from such studies indicate that patients with PTSD exhibit exaggerated automatic responses within the amygdala to general threat-related stimuli, dissociated from medial frontal activation. Furthermore, research in this area has suggested that the magnitude of amygdala response may be able to distinguish subjects with PTSD from those without PTSD, leading to the conclusion that the amygdala plays a fundamental role in the pathophysiology of PTSD.

Although functional neuroimaging studies of patients with PTSD have largely been performed in adult populations, a few have aimed to investigate whether adolescents who developed PTSD after experiencing traumatic events show a differential brain response compared to those who did not. Findings appear to be consistent with those from studies of PTSD in adults.

Magnetic resonance spectroscopy studies Significant biochemical changes affecting the function of an anatomical structure may not be reflected in volumetric changes. Supportive and connective cells and other structural elements may maintain the general shape or volume of a structure despite significant changes in neuron number, size, or viability. One way to assess this possibility is through MRS.

The few MRS studies that have been conducted in PTSD have showed lower levels of N-acetyl-aspartate (NAA) in the hippocampus of patients compared with healthy controls. Research has also examined the relationship between hypothalamic-pituitary-adrenocortical measures and hippocampal NAA in those with and without PTSD. Such research has shown that cortisol levels were positively correlated with hippocampal NAA. This suggests that within the normal range, cortisol may have a trophic effect on hippocampal neurons. This relationship between cortisol and hippocampus may vary depending on the levels of glucocorticoids in particular diagnostic groups. MRS findings so far suggest that hippocampal neuronal viability, density, and function are impaired in PTSD, consistent with the volume loss in hippocampus reported by MRI studies.

Depression

One of the more robust findings in depression research is an impaired regulation of stress hormones. Neuroimaging in MDD has brought about a clearer understanding of the impact of stress mechanisms on the brain. The role of stress in depression is complex and varies with the frequency or duration of stressful life events and the length and number of cycles of depressive episodes. Pooling individuals who have similar lifetime stress burdens and a comparable clinical history for depression in case control imaging studies may be potentially informative, but quantifying lifetime stress burden is challenging and rarely done, as there is no satisfactory, i.e., simple and valid, proxy measure. Interindividual response to stress varies widely, and stressful events are experienced differently from one individual to another.

Structural imaging studies Glucocorticoid steroid receptors are highly concentrated in the hippocampus; the excess of glucocorticoids associated with

repeated stress is neurotoxic in animal models, contributing to local neuronal dysfunction and ultimately cell death. A large number of MRI studies have looked for differences in regional brain volumes, especially hippocampal volume, between depressed subjects and comparison groups, usually healthy volunteers. Less attention has been paid to exploring relationships between hippocampal volume and neuropsychological impairment, hypercortisolism, stress burden of repeated depressive episodes, and estimating volumes of other parts of the brain, for example, the amygdala.

Although brain volume reductions have been reported for frontal cortex, amygdala, and limbic areas including subgenual cingulate cortex, hippocampal reductions, mainly on the left, have been replicated most frequently (Figure 2). Hippocampal volume differences are associated with length and number of depressive episodes and cortisol concentration, but are not associated with age. Evidence from meta-analytic studies suggests that including the amygdala in a combined amygdala-hippocampal structural analysis decreases the ability to detect volumetric differences in either structure. In depressed patients, poor verbal memory performance and later dementia were correlated with hippocampal gray matter reduction, although the evidence for mediation by cortisol is limited.

Functional imaging studies Functional imaging studies (PET) of patients with MDD have generally reported increased cerebral blood flow and metabolism in the amygdala, but reduced flow in dorsolateral prefrontal cortex and anterior cingulate cortex. Furthermore, elevated amygdala activity in MDD was positively correlated with both depression severity and plasma cortisol concentrations.

Although increased amygdala activity could represent an exaggerated response to the stress of imaging itself, amygdala metabolism has been found to be elevated in MDD compared with controls during wakefulness and during rapid eye movement sleep. Treatment with antidepressants reduces metabolism in the anterior cingulate cortex and amygdala to normal levels, with clinical improvement and a reduction in hypercortisolism. Metabolism in the hippocampus of MDD patients has been less well investigated than in the amygdala, but both reductions and increases have been found in the hippocampi of MDD subjects.

Neuroreceptor imaging studies In contrast to structural and functional imaging, there has been relatively little exploration of the role of neurotransmitter systems in the regulation of depression. Both SPECT and PET have been used with radiotracers to investigate

Figure 2 Left (medial) temporal reduction of gray matter density in chronic treatment resistant depression. Data presented in Shal et al. (1998, 2002).

mainly the serotonergic and dopaminergic systems. Serotonin (5-HT) is implicated in the mechanism of depression and clinically modified with selective serotonin reuptake inhibitors (SSRIs). Primarily, the postsynaptic 5-HT_{1A} and 5HT_{2A} receptors have been explored and are among several that are known to mediate serotonergic neurotransmission.

5-HT_{1A} is abundant in the limbic system and, in particular, the hippocampus. In animal studies, stress negatively modulates 5-HT_{1A} receptors through corticosteroid secretion. Decreases in 5-HT_{1A} binding associated with chronic stress can be prevented in animals with antidepressant treatment. Changes observed in the hippocampi of suicide victims with a history of depression have been found to be similar to changes associated with chronic stress in animals, i.e., abnormally decreased hippocampal 5-HT_{1A} levels, suggesting that alterations in hippocampal 5-HT_{1A} levels and in the corticoid receptor balance may be a mechanism by which stress triggers depressive episodes.

In depression, decreased 5-HT_{1A} binding has been found in multiple brain regions, including mesiotemporal cortex, midbrain raphe, as well as hippocampus/parahippocampus, postcentral gyrus, and occipital pole. Differences between mean stressed plasma cortisol concentrations in depression and healthy volunteers are not correlated with reduced 5-HT_{1A} receptor binding. 5-HT_{1A} receptor-binding potentials have been found to be reduced across multiple brain regions in both medicated (SSRIs) and unmedicated depressed subjects compared with healthy volunteers.

Reduced 5-HT_{1A} receptor binding was unchanged by treatment with SSRIs. Results in imaging studies of 5-HT₂ and D₂ receptor binding have been less conclusive in depression and may be associated with subsyndromes.

MRS studies MRS has been used to identify neurochemical effects of treatment and predictors of treatment response with MDD and BDD. Significantly smaller hippocampal regions accompanied by a corresponding significantly elevated choline/creatinine ratio have been found in drug-resistant severe MDD compared with matched healthy controls. However, reductions in choline have also been reported so that there is no current consensus.

Cushing's Disease/Syndrome

Cushing's syndrome (CS) results from the chronic exposure to higher than physiological levels of endogenous cortisol, the naturally occurring glucocorticoid (GC), which often produces neuropsychological and emotional changes in affected patients. Because patients with CS have high circulating levels of endogenous cortisol, they offer an opportunity to study cognitive abnormalities after chronic exposure to elevated levels of cortisol. Structural imaging studies in patients with CS have documented atrophy of the hippocampus. Studies looking at neuronal dysfunction and loss as a result of endogenous levels of glucocorticoids, especially within the hippocampus, may provide a better general understanding of the effects

of high levels of glucocorticoids on hippocampus-mediated cognitive functions and the pathophysiology of CS. Furthermore, patients with CS provide a unique opportunity to study the reversibility of the effects of endogenous cortisol in humans. The potential for reversibility of glucocorticoid-induced alterations of hippocampal structure and function has important theoretical and clinical implications.

In a seminal study, Starkman and colleagues used MRI to investigate the reversibility of cortisol-induced changes in hippocampal volume in 22 patients with Cushing's disease who were examined prior to and following treatment. The results from this study indicate that the hippocampal formation is able to increase in volume following sustained reduction of previously elevated cortisol concentrations. With remission of Cushing's disease, hippocampal volume increased in patients up to 10%. Furthermore, the percent increase in hippocampal volume was significantly correlated with the magnitude of change in urinary free cortisol level, a relationship that was region specific, as there was no significant association between change in cortisol and change in caudate head volume. These results are consistent with observations in animals and demonstrate that hippocampal change in response to sustained elevation of cortisol is reversible, at least in part, once cortisol levels have decreased to normal. However, patients were not imaged prior to the onset of Cushing's disease. It is, therefore, not known whether the increase in hippocampal volume that was observed in this study represents partial or complete reversibility of the decrease of hippocampal volume that occurred as a result of exposure to high levels of cortisol.

Human Aging

Despite evidence of memory decreases during pharmacological glucocorticoid treatment and correlations between memory and cortisol levels in certain disease conditions, such as CS, it remains unclear whether exposure to the endogenous glucocorticoid cortisol levels seen during physical and psychological stress in humans can inhibit memory performance in otherwise healthy adults. Results from research in this area has indicated that exposure to cortisol at doses and plasma concentrations associated with physical and psychological stress in humans can reversibly decrease verbal declarative memory function in otherwise healthy humans. It has been suggested that the results from this area of research are relevant to the interpretation of decreased memory performance during periods of extended stress in humans, in which plasma cortisol elevations are present throughout memory encoding and retrieval processes.

There is further evidence that elderly human subjects with high cortisol levels increasing over the years have impaired hippocampus-dependent memory and show a reduction in hippocampal volume compared with elderly subjects who have moderate cortisol levels that have been decreasing over the years.

One of the main issues that have arisen from research relating to reduced hippocampal volume and impairment on hippocampus-mediated memory function in elderly populations is whether deficits are due to the atrophying effects of increased cortisol levels or some other underlying organic brain pathology such as dementia of the Alzheimer's type. Because age is a risk factor for dementia, it becomes increasingly difficult in older adults to determine the etiology of reduced hippocampal volume and hippocampus-mediated memory.

Conclusions

Technical advances in the field of neuroimaging have made it possible to examine brain activity and brain structure in life. It is possible to measure the concentration of biologically relevant molecules and the number of receptors in a particular neurotransmitter system. The usual way of employing these methods is by selecting a group of patients and a matched control group and comparing them with regard to an objective measure derived from the brain image. There are two possible limitations in our ability to draw valid conclusions from such data. The first is that because of the cost of imaging studies, a relatively small sample from the larger population of patients has to be selected. Whether the sample actually studied is representative for the disorder depends on whether its selection has been subject to any bias. Many sources of bias can occur in the selection for an investigation that needs a significant amount of cooperation from subjects. The ideal, i.e., that subjects are randomly selected from the underlying population, is virtually never achieved, so that conclusions always have to be tentative and need independent replication. The other limitation is inherent in the cross-sectional design of virtually all studies. An association study usually does not allow for any establishment of causality. Hippocampal atrophy may be the result of chronic stress, or it may be the predisposing factor that makes subjects vulnerable to developing the stress-related disorder. To circumvent this difficulty, longitudinal follow-up designs are necessary. These are costly and require an early identification of subjects at risk. They are also likely to require a longer time to come to fruition, so regarding the relevance of the changes described to date, the jury is still out.

Glossary

Chaperone machine A functional chaperoning complex formed by the chaperone Hsp70(DnaK), the co-chaperones Hsp40(DnaJ), and a nucleotide-exchange factor, for example, GrpE in prokaryotes and BAG-1 (BCL2-associated pathanogen, where BCL2

	stands for B cell lymphoma 2) and HspBP1 (Hsp70-binding protein 1) in eukaryotes.
<i>Chaperonin</i>	A molecular chaperone belonging to the 60-kDa family.
<i>Chaperonin system type (group) I</i>	A chaperoning complex formed by the 60-kDa chaperonin and a 10-kDa co-chaperonin (e.g., GroEL and GroES, respectively, in bacteria) that is present in bacteria, in the bacterial-related eukaryotic-cell organelles, and in some archaea.
<i>Chaperonin system type (group) II</i>	A chaperoning complex formed by subunits of the 60-kDa family in archaea (i.e., the thermosome subunits) and by related proteins of various sizes in the eukaryotic cell cytosol.
<i>Molecular chaperone</i>	A molecule that assists polypeptides in the process of folding to achieve a final functional conformation or to regain such conformation after reversible denaturation. The prototype is the stress protein called Hsp70(DnaK).
<i>Phylogenetic domain</i>	The highest order of classification of all living cells (domain, kingdom, phylum, class, order, family, genus, species) that represents the major evolutionary lines of descent, or phylogenetic lineages. Three domains have been identified: Bacteria (or eubacteria), Archaea (archaeobacteria), and Eucarya (eukarya, eukaryotes); the former two are prokaryotes.
<i>Stress (heat shock) proteins</i>	The products of the stress (heat shock) genes. Many of these are molecular chaperones, for example, the components of the chaperone machine.
<i>Stress (heat shock) response</i>	The series of intracellular events caused by cell stressors. One of the most prominent of these events is the induction of the stress (heat shock) genes, resulting in the production of stress (heat shock) proteins.

Proteins

A protein molecule is a chain whose links are amino acids. The number, type, and order of amino acids in the chain are specified by the gene that encodes the protein, and they determine the primary structure. To reach a functional status, a protein must acquire higher levels of complexity. It must fold onto itself to achieve secondary and tertiary levels of structure. In addition, some proteins must associate with others to form a quaternary structure before they can become fully functional.

The functional conformation of a protein, once acquired, may be partially or completely lost in a process called protein denaturation. This can happen when a cell is stressed. There are a number of cell stressors of a physical or chemical nature that cause

protein denaturation. Although the information necessary to achieve a final functional conformation is contained in the primary structure, many proteins need assistance to fold properly or to refold after reversible denaturation. This assistance is provided by molecular chaperones.

Definition

Chaperone proteins, or molecular chaperones, are proteins that assist others to fold properly during or after synthesis, to refold after partial denaturation, and to translocate to the cellular locales at which they reside and function. Chaperones are also involved in the regulation of their own genes and in the presentation of proteins destined for degradation by proteases. Some chaperones are themselves proteases.

Many chaperones are stress (heat shock) proteins, in that they increase in quantity on cell stress (also termed heat shock, although heat is not the only stressor known) so as to counteract the protein-denaturing effects of stressors (e.g., heat, alcohol, ischemia-hypoxia, heavy metals, and hypersalinity). For this reason, stress proteins and molecular chaperones are usually treated together, as a single large group of heterogeneous components, termed Hsp (for heat shock protein). Thus, there are many cell stressors that cause stress or heat shock and many stress or heat shock proteins, but not all of the latter are molecular chaperones. Likewise, not every molecular chaperone is a stress protein.

As may be inferred from their multiplicity of function, molecular chaperones are promiscuous; they interact with a variety of molecules. They are also ubiquitous; they occur in all cells, tissues, and organs, with very few known exceptions. Furthermore, molecular chaperones are present in the various compartments of the eukaryotic cell, nucleus, cytosol, and organelles such as mitochondria and chloroplasts; they are also present in the prokaryotic cell cytoplasm and periplasm.

Classification

Stress proteins, including the chaperones, are grouped into families on the basis of similarities in molecular masses ([Tables 1 and 2](#)). The genes encoding most of these proteins are stress-inducible, but they are also expressed constitutively (i.e., in the absence of stress) at lower levels.

The best studied are the Hsp70 and Hsp60 families, but considerable progress has also been made in the investigation of proteins belonging to other families, for example, Hsp40 and Hsp90, the high-molecular-weight proteases, and the small heat shock proteins (sHsp).

Table 1 Stress (heat shock) proteins and chaperones in prokaryotes

Family		Examples	
Name(s)	Mass (kDa)	Bacteria	Archaea
Heavy; high molecular weight; Hsp100	100 or higher	Clp	No ^a
Hsp90	81–99	HtpG	No
Hsp70; DnaK; chaperones	65–80	DnaK; Hsc66	Hsp70(DnaK) ^b (only some species)
Hsp60	55–64		L
Chaperonins group I		GroEL	GroEL (only some species)
Chaperonins group II		No	TF55; thermosome subunits (up to five)
Hsp40; DnaJ	35–54	DnaJ	Hsp40(DnaJ) (only some species)
Other	≤34		
small Hsp; sHsp		sHsp: Hsc20; Hsp15; alpha-crystallin family; other	sHsp: Hsp16.5; α-crystallin family; other
miscellanea		Hsp33; GroES; GrpE; PPIase; PDlase; lbpA/B; SecB; other	GroES (only some species); GrpE (only some species); PPIase; PDlase; prefoldin, 1 or 2 subunits; Sso7d

^aNo indicates not yet found, or not yet investigated in many species.

^bArchaeal species with Hsp70(DnaK) also have Hsp40(DnaJ) and GrpE; no species has yet been found having only one or two of these three chaperones.

^aChaperones build multimolecular assemblies to exercise their functions. These assemblies are formed by identical or different chaperone molecules (subunits) and by cofactors. In addition, these chaperone complexes interact with other chaperone complexes (networking) and with the protein-degradation machinery (e.g., the ubiquitin–proteasome system) to integrate the protein quality-control system of the cell. Synonyms are given in parentheses. No indicates not yet found, or not yet investigated in many species.

^bIn addition to the chaperones listed in the endoplasmic reticulum column, this organelle also has Grp58(Erp57) and lectins (calreticulin and calnexin, approximately 45 and 60 kDa, respectively) that assist, together with associated factors, the folding and oligomerization of many glycoproteins.

Biology

Chaperones and stress proteins can be viewed from an evolutionary-phylogenetic standpoint, while keeping in mind that the separation between prokaryotes and eukaryotes is not absolute, inasmuch as the eukaryotic cell contains components of prokaryotic ancestry. For instance, the mitochondrion is the remnant of an ancient alpha-proteobacterium that entered into a symbiotic association with a primitive eukaryotic cell. Similarly, the chloroplast descends from a primitive symbiotic cyanobacterium. Even the eukaryotic nucleus contains, in its DNA, genes that were derived from bacteria. In this regard, genes encoding chaperones of the Hsp60 and Hsp70 families are of particular interest. These chaperones are present in the mitochondria, chloroplasts, endoplasmic reticulum (ER), and other organelles (see [Table 2](#)), but their genes reside in the nucleus. These genes are transcribed in the nucleus, but the chaperones are synthesized in the cytosol and are finally translocated to the destination organelle. In fact, it has been the comparative analyses of Hsp70 and Hsp60 amino acid sequences that have convincingly shown the origin of the genes that encode these proteins and have provided strong support for the idea that the eukaryotic cell is an assemblage of diverse parts, several of which are prokaryotic in origin.

Phylogenetic Domains

Since the late 1970s, the idea that all living cells can be sorted into three main lines of evolutionary descent, or phylogenetic domains, has gained acceptance, although many points remain controversial and the boundaries between domains at the beginning of evolution are less well-defined than was initially believed. Nevertheless, it is helpful to think of stress proteins and chaperones within the context of the three domains, Bacteria (eubacteria), Archaea (archaeobacteria), and Eucarya (eukaryotes) – the former two being prokaryotes. Why is this helpful? Because archaea (i.e., the members of the domain Archaea) are indeed different from bacteria and eucarya or eukaryotes (i.e., the members of the domains Bacteria and Eucarya, respectively) in terms of the Hsp70 and Hsp60 chaperones. For example, bacteria possess the Hsp70 (also named DnaK), Hsp40 (also named DnaJ), and GrpE stress proteins that constitute the molecular chaperone machine (KJE) and the Hsp60–Hsp10 molecules that constitute the GroEL/S or chaperonin group I system. In contrast, many archaea do not have the chaperone KJE or GroEL/S, and eukaryotes have GroEL/S homologs only inside their organelles. It is noteworthy that many archaea do not have KJE because this

machine is present in all bacteria and eukaryotes without any known exception. Also remarkable is the presence of GroEL/S in some archaea because until recently it was thought that this chaperoning complex was exclusive to the bacteria and bacteria-related organelles.

The structures and functions of the molecular chaperone machine and of the chaperonin system type I are relatively well characterized in the bacterium *Escherichia coli*. There is also considerable information on the eukaryotic Hsp70 complex and on the chaperonin system type II. Intriguingly, some archaea either do not have an identifiable chaperone machine or have one of bacterial type with the Hsp70(DnaK), Hsp40(DnaJ), and GrpE components, but they all have a type II chaperonin system. The fact that archaea have a eukaryotic type of chaperonin system is remarkable because archaea, like bacteria, are prokaryotes.

Also interestingly, eukaryotes have the bacterial type of Hsp60 chaperonin system in their organelles, bearing witness to the bacterial origins of the latter. Thus, one of the most exciting fields of biology at present is the analysis of chaperonins and chaperones in organisms representing the three phylogenetic domains and domain branches to understand the evolution of these molecules and also to elucidate the relationships among species, and between organelles and their prokaryotic ancestors.

Another point of great interest, from both the evolutionary and the physiological standpoints, is that a number of archaeal species do not have Hsp70 (DnaK) or the other components of the chaperone machine, Hsp40(DnaJ) and GrpE. This peculiarity is remarkable because it represents the only exception known to the rule that every organism has an Hsp70 system (in fact, Hsp70 is considered one of the most highly conserved proteins in nature). The absence of the gene triad that encodes the components of the chaperone machine is noteworthy also because it raises the issue of how these organisms can achieve protein biogenesis and survive stress without the molecular chaperone machine.

Physiology

Prokaryotes, with few exceptions, have only a single *hsp70(dnaK)* gene, which is active under normal physiological conditions and is activated further by stressors. In the latter case, an increase in Hsp70 (DnaK) over the basal or constitutive levels is observed; it may be due to increased transcription and/or translation, and/or decreased mRNA and/or Hsp70(DnaK) degradation. In contrast, eukaryotes have more than one *hsp70(dnaK)* gene. Essentially, one gene is active physiologically and responds to

physiological signals (it is said to be constitutively induced), whereas the other gene is induced by stressors. The former gene is designated cognate *hsp70*, abbreviated *hsc70*, and the protein is termed Hsc70. In fact, eukaryotic cells may have more than one representative of the two types of the *hsp70* gene, and both types may respond to physiological stimuli, such as stimuli derived from cell-cycle and cell-differentiation events. Therefore, *hsp70(dnaK)* is also interesting from the point of view of cell physiology during development and histogenesis and is an important player in pathology and disease.

Pathology and Medicine

Molecular chaperone genes and proteins, as well as chaperonins and other stress genes and proteins, are being studied at the present time to determine their roles in the maintenance of health and in the development of disease. It is conceivable that the failure of the chaperoning processes due to a defective chaperone (chaperonopathy) will lead to the accumulation of misfolded proteins that do not function or to misplaced proteins that do not reach their destination in the cell to function properly. In both instances, the accumulation of nonfunctional proteins will encumber the cell and disturb its normal physiology. This is why protein degradation is also an important cellular process, part of which depends on molecular chaperones.

Chaperonopathies may be caused by genetic defects (e.g., chaperone-gene mutation) or by post-translational modifications of the chaperone molecule, such as those observed in the elderly as a manifestation of the aging process, which is characterized by a progressive accumulation of biochemical damage in many proteins.

Molecular chaperones may be exploited as tools for preventing protein denaturation or for restoring partially denatured proteins (e.g., during surgery) when ischaemia-hypoxia (a strong cell stressor) is unavoidable. The use of chaperones for prevention and treatment of pathological conditions is emerging as a new medical field: chaperonotherapy.

Mechanism

The mechanism of action of chaperones at the molecular level has not been fully elucidated for any organism or any particular family of chaperones, but there is considerable information on the Hsp70(DnaK) and Hsp60 (chaperonin) systems in *E. coli*. How do chaperones interact to help a polypeptide to acquire its final three-dimensional (native) configuration, based on its primary structure? It is known that chaperones

neither provide steric information nor form part of the final product. The Hsp70(DnaK) system in the cytosol is believed to bind nascent polypeptides so as to prevent their aggregation, either among one another or with other polypeptides in the immediate vicinity. In this manner, the Hsp70(DnaK) machine maintains the newly made polypeptide in a folding-competent status. In contrast, the Hsp60 (chaperonin) system GroEL/S acts posttranslationally and assists in the folding of polypeptides ranging in size from 25 to 55 kDa. Hence, without chaperones, most polypeptides would aggregate and the few that would proceed in the right direction toward achieving a physiologically active conformation would do so very slowly and inefficiently. Within this context, it is easy to realize that chaperones and chaperonins, and other stress proteins such as the sHsp, play a critical role in cell survival during stress, when the tendency toward protein denaturation and aggregation is strong.

The binding of polypeptides to, and their release from, Hsp70(DnaK) is ATP-dependent and involves the other members of the Hsp70(DnaK) machine, Hsp40(DnaJ), and a nucleotide-exchange factor (e.g., GrpE in prokaryotes). Hsp40 binds the polypeptide in need of assistance and presents it to Hsp70-ATP complex. As this complex binds the Hsp40-tagged polypeptide, Hsp40 catalyzes ATP hydrolysis, which increases the strength of the binding between Hsp70-ATP and the polypeptide. GrpE then comes into action and catalyzes the exchange of ATP for ADP on Hsp70. When Hsp70 is once again complexed with ATP, its affinity for the polypeptide diminishes and the latter is released, either because it has folded correctly or because it has to be processed further by the Hsp60 system GroEL/S.

The GroEL/S complex in *E. coli* is a cylindrical barrel. GroEL (the Hsp60 component) forms two heptameric rings with a central cavity. GroES (the Hsp10 subunit) forms a single heptameric ring and serves as a lid for the two-ring GroEL barrel. The polypeptide-folding mechanism is believed to be as follows. The unfolded polypeptide reaches the entrance to the GroEL barrel either unassisted or ushered by the chaperone machine, enters into the cavity, and binds to hydrophobic patches in the wall of the barrel. The GroES ring, together with ATP, then binds to the GroEL cylinder, thereby closing it. Thus, a hydrophilic folding chamber (also called cage) is created, and the polypeptide is in an environment in which it becomes soluble and can fold correctly. ATP binding to the other GroEL ring releases GroES, opening the barrel, and this allows the folded polypeptide to escape into the cytosol. The cycle is repeated if the folding process was incomplete.

The details just described have been inferred from experiments *in vitro* with *E. coli*. It is not known to what extent the *in vitro* findings reproduce the *in vivo* mechanisms. Also, the mechanism of Hsp70–Hsp60 chaperoning in locales other than the cytosol, for example, in the mitochondria, differs from the mechanism described earlier. Similarly, the mechanisms of action of the other families of chaperones are also different in many details.

We may conclude, from studies pertaining to the *E. coli* cytoplasm, that, whereas the Hsp70(DnaK) chaperone machine intervenes early in protein synthesis (during translation) to prevent aggregation of the majority of the nascent polypeptides, the Hsp60 chaperonin system acts later. The GroEL/S complex intervenes posttranslationally and only to assist that fraction of the new polypeptides that reach it either unassisted or ushered by the chaperone machine. The rest of the newly made polypeptides in *E. coli* do not use the GroEL/S chaperonin system, and they probably fold in the cytosol assisted only by the chaperone machine.

To Fold, Refold, or Degrade

The protein content and quality of a cell vary according to the cell's needs imposed by physiological (e.g., cell cycle or differentiation stage) and environmental changes (e.g., nutrient limitation, pH drop, or temperature or osmolarity upshift). The diverse array of proteins and the quantities of each of these must be adjusted precisely to the requirements of every moment of the cell's life. This delicate balance is achieved by various complementary, coordinated mechanisms that effectively either increase or decrease the concentration of any given protein in its native functional conformation in any given cell locale. Also, when proteins are damaged by stressors, they must be restored to normality (native as opposed to denatured or unfolded, or misfolded, status) or they must be eliminated if the damage is too severe and beyond repair.

Stress proteins, particularly those that are molecular chaperones, play a key role not only in protein biogenesis and in restoring partially damaged proteins to a functional pool, but they are also involved in eliminating molecules that cannot be recovered. For the latter purpose, stress proteins act in conjunction with proteases or they use their own proteolytic power (many stress proteins are proteases, and some are both chaperones and proteases). Because of this dual role – assistance in the generation and recovery of polypeptides, as well as in their destruction – stress proteins are essential tools by which the cell maintains its protein balance.

Proteins for degradation are either normal or abnormal. Many normal proteins have a short life span; they are naturally unstable, as required by their transient tasks inside the cell. Examples are transcription regulatory factors, termed activators, that need to be eliminated to downregulate the expression of certain genes. The same is true for some repressors, which have to be removed when the gene that they regulate must be upregulated or induced. Many abnormal (denatured) proteins are generated by stress, as noted earlier. In addition, abnormal proteins may appear in the cell in the absence of stress, as a result of genetic mutations or of transcriptional, translational, and/or processing errors.

Whatever the case, unfit or unnecessary proteins must be either eliminated or restored to a functional status; for each one, the cell must make the decision as to whether to try to fold, or refold, or to degrade. In the last alternative, the cell will not only be freed from potentially detrimental molecules or molecular debris, but it will at the same time acquire building blocks to synthesize new molecules. Proteins destined for degradation must be recognized by proteases; for this purpose, they have tags that are seen by the proteolytic enzymes. Some molecular chaperones provide the tag and present the protein for degradation to the protease.

In conclusion, molecular chaperones not only assist in the generation of protein molecules, but they also contribute to the elimination of proteins when they are potentially dangerous or no longer necessary (dispensable) to the cell.

Impact of Defective Chaperones
Examples of Chaperonopathies

Glossary

Acquired chaperonopathy
A chaperonopathy that is due to a structural defect in a molecular chaperone acquired during the life of the individual and that is not passed on to the offspring, i.e., is not hereditary.

Chaperone complex

A team of two or more chaperones, cochaperones, and cofactors assembled to carry out the chaperoning process.

Chaperone networking

The interaction of a chaperone complex with another, distinct chaperone complex, or with a protein-degrading complex.

Chaperonopathy
Client polypeptide or substrate

A pathological condition in which a molecular chaperone is abnormal.

A polypeptide recognized by a chaperone or chaperone complex as needing assistance for folding or refolding, or as destined for degradation.

Dysregulatory chaperonopathy
Genetic chaperonopathy

Increase or decrease in the levels of a molecular chaperone caused by up- or down-regulation, respectively, of its parent gene.
A chaperonopathy characterized by a structural defect in a molecular chaperone due to a genetic (hereditary) cause, such as a gene mutation.

<i>Genetic polymorphism</i>	The occurrence, in a population of organisms of the same species, of more than one allele or genetic marker at the same locus. A polymorphism is distinguished by the fact that the least frequent allele or marker occurs more often than if it were due only to mutation.
<i>Primary chaperonopathy</i>	A condition in which the molecular chaperone pathology is not the consequence of another pathological disorder.
<i>Proteinopathy</i>	A pathological condition characterized by the occurrence of an abnormal protein molecule, usually with a tendency to misfold, aggregate, and precipitate.
<i>Secondary chaperonopathy</i>	A condition in which a molecular chaperone pathology is associated with another disorder and is the consequence of it, rather than its cause.

Definitions and Classifications

A chaperonopathy can be defined as a pathological entity characterized by a defect in a chaperone or co-chaperone. In structural chaperonopathies, the structure of the chaperone molecule is altered because its

Figure 1 Schematic (not to scale) of the life of a protein, from parent gene to fully folded molecule to degradation, in a eukaryotic cell. Crucial steps that require chaperone assistance, and sites of stress impact whose adverse effects might enhance senescence and/or disease development, are noted. 1, Protein-coding gene (brown rectangle) with two introns (black). 2, Transcription. 3, Primary transcript (pre-mRNA), still with the two introns. 4, Pre-mRNA processing, including intron removal and exon splicing. 5, Mature mRNA (brown rectangle). 6, mRNA transport from nucleus to cytosol via nuclear pore complex. 7, mRNA translation on the ribosome (light blue). 8, Nascent polypeptide (orange, thick wavy line) emerging from the ribosome, when folding begins, assisted by ribosome-associate chaperones. 9, Newly made polypeptide released by the ribosome on its way to posttranslational folding. 10, The same polypeptide farther along the folding pathway. 11, New protein, correctly folded into its tertiary structure (native, functional conformation); some proteins achieve a functional status by forming oligomers (quaternary structure), 11a. 12, Some

parent gene is mutated, or because of another mechanism acting beyond the DNA, namely, during or after gene transcription. An example of the latter post-DNA mechanisms resulting in a structural defect in the chaperone molecule is an aberrant posttranslational modification.

Other chaperonopathies do not involve a structural modification of the chaperone molecule itself, but rather are characterized by quantitative (increase or decrease) and spatial (distribution in cells and tissues) changes. Levels of chaperones may be elevated or

proteins are translocated into organelles (e.g., mitochondrion; yellow) through the organellar membranes. 13, Aggregate, formed by unfolded or misfolded polypeptides. 14, Precipitate of aggregated polypeptides (protein deposit or inclusion body). 15, Unfolded or partially folded polypeptides freed from the aggregates by the action of aggregate-dissolving mechanisms involving chaperones. 16, Protein degradation products, depicted inside a shaded area that symbolizes a dynamic graveyard, in which degradation proceeds from oligopeptides of decreasing lengths down to individual amino acids, which will ultimately be recycled as building blocks for new proteins, in step 8. Some of the known proteolytic machineries found in prokaryotic and eukaryotic cells are depicted: the proteasome-ubiquitin system (magenta), tricorn protease (light green), and other proteases (dark blue). Also, the proteasome (immunoproteasome) generates short antigenic peptides by cleaving large protein antigens for use by antigen-presenting cells. Black solid arrows: physiological route from gene to functional protein. Black wavy arrow: translocation pathway from cytosol into an organelle, for example a mitochondrion. Green solid arrows: critical steps that require chaperone assistance. Green broken arrows: critical steps for which chaperone assistance is probably needed but not yet fully documented. Red arrowheads: molecule (or structure, function, pathway) adversely affected by stress. Red arrows: route from unfolded, partially folded, or misfolded proteins toward aggregation; this route is followed by abnormal proteins even in the absence of stress, and by normal and abnormal proteins that have been denatured by stress. Blue solid arrow: route from protein aggregation toward precipitation of aggregates (inclusion body formation). Violet arrows: routes to protein degradation followed by normal proteins in physiological cellular processes (e.g., in gene regulation, via activator or repressor degradation) and by abnormal proteins that cannot be folded or rescued (refolded) by chaperones (there should also be a similar arrow from 9 to 16, which was omitted for the sake of clarity). Green wavy arrows: participation of chaperones in protein degradation pathways. Black dotted arrows: recovery route from aggregate to free polypeptides to refolding; possibly this route is very actively utilized in proteinopathies, as the chaperoning systems attempt to rid the organism of pathologic aggregates, and to avoid protein deposition. A similar course of events may occur during senescence, with the caveat that the required chaperoning systems probably become less and less efficient with age. Black discontinuous (squares alternating with solid circles) arrow from 14 to 15: possible but improbable recovery route from protein deposit toward the release of free, re-foldable polypeptides. Note that the need for chaperone assistance and the stress-sensitive sites are widespread. Modified from Macario, A. J. L. and Conway de Macario, E. (2002). Sick chaperones and ageing: a perspective. *Ageing Research Reviews* 1, 295–311, with permission.

Table 1 Genetic chaperonopathies and human chaperone gene polymorphisms^a

<i>Chaperone Hsp gene/protein affected</i>	<i>Disease/syndrome</i>
sHsp Hsp27	Williams Charcot-Marie-Tooth Distal hereditary motor neuropathy
Alpha crystallins	Childhood cataracts
Alpha-B-crystallin	Desmin-related myopathy
Hsp22	Distal motor neuropathy
Chaperone cofactors for microtubule biogenesis	
Cofactor C (RP2)	X-linked retinitis pigmentosa
Cofactor E	Sanjad-Sakati and Kenny-Caffey Progressive motor neuronopathy
Chaperonin of group I, Hsp60	
Mitochondrial Hsp60 (Cpn60)	Hereditary spastic paraplegia
Chaperonin of group II, CCT subunits	
Alpha subunit	McKusick-Kaufman and Bardet-Biedl
Delta subunit	Hereditary sensory neuropathy
Peptidyl-prolyl <i>cis-trans</i> isomerase (FKBP)	Leber congenital amaurosis
<i>Genetic polymorphism</i>	<i>Abnormality/disease</i>
<i>hsp70-1</i> promoter region, allele (A)-110	Does not favor longevity in women
<i>hsp70-Hom</i> , T247C, threonine instead of methionine at position 493	Does not favor longevity
<i>hsp70-1</i> , promoter region, allele (C)-110	Associates with Parkinson's disease in Taiwanese

decreased in cells in certain diseases compared with levels in the same cells from healthy individuals. Likewise, the distribution pattern of a chaperone inside a cell (e.g., within the cytosol, or within organelles), or in various cell types and tissues, may differ from that typical of healthy counterparts.

Quantitative alterations may be caused by up- or downregulation of the chaperone gene or by other posttranscriptional mechanisms such as increased (or decreased) stability of mRNA and/or protein or translation rate.

In the case of chaperones whose parent genes are stress inducible, i.e., genes that respond to stressors and are active in the stress response, quantitative changes may be due to up- or downregulation of stress gene regulators such as the HSF (heat shock factor) genes in eukaryotes. If a chaperone gene is up- or downregulated by its own regulatory mechanisms, the resulting pathologic entity will be a dysregulatory chaperonopathy.

From another standpoint, chaperonopathies may be characterized as primary or secondary. The former are due to defects inherent in the chaperone molecule, defects that have an impact on cells and tissues, and thus becomes a central part of pathogenesis. Examples of primary chaperonopathies are those due to inherited defects in the chaperone-encoding genes.

Secondary chaperonopathies are the consequence of a disease rather than the reverse; the defective chaperone is not a primary factor in pathogenesis, but it may contribute to it. Among these are chaperonopathies associated with the process of aging and chaperonopathies caused by stressors that damage the chaperone molecule. Likewise, some quantitative chaperonopathies may be classified as secondary.

Another cause of chaperone failure may reside not in the chaperone itself, but in the client polypeptide. At least two causes have been recognized. (1) The substrate is genetically defective and lacks the segment of sequence that would be recognized by the chaperone machine to proceed with folding; consequently, the client polypeptide remains unfolded and malfunctioning. (2) The substrate does interact with the chaperone, but because the substrate has certain biochemical-biophysical characteristics, this interaction inhibits rather than initiates the chaperoning process that leads to folding.

Similarly, chaperonopathies may be classified as genetic or acquired. The former are due to a genetic defect, e.g., mutation in the chaperone-encoding gene itself or in the gene encoding a chaperone gene regulator (e.g., the HSF gene). Polymorphisms in these genes may also account for some chaperonopathies.

A genetic chaperonopathy can be described at any of several levels: (1) a locus, gene, or exon that is altered, causing the absence of a chaperone molecule, or its structural abnormality, leading to malfunction; (2) a gene product, from primary transcript to protein (pre-mRNA, or mRNA, or protein, Figure 1) can be structurally and functionally abnormal; (3) a chaperone complex or chaperone network that is structurally

Table 2 Examples of chaperonopathies associated with aging^a

<i>Hsp/chaperone/HSF</i>	<i>Experimental-clinical observation</i>	<i>Conclusion</i>
Alpha-A-crystallin	Low levels and PTM and truncation in aged retina	Senescence-associated quantitative and qualitative changes
Alpha crystallins	Decreased solubility and PTM in the eye lens	Senescence-associated qualitative changes
Hsp70 and Hsc70	Aged cultured hepatocytes, melanocytes, and skin fibroblasts, and fibroblasts from old humans: low response to heat shock	Senescence-associated quantitative and functional changes
Hsc70	Low levels in retinas from aged humans and monkeys	Same as above
Hsp27, Hsp70, Hsc70,	High basal levels in aged, cultured, RMHS-treated fibroblasts from humans	Quantitative and functional changes due to aging and chronic stress
Hsp90	Decreased with RMHS and aging in human skin fibroblasts	Same as above
Hsp90	Low levels and chaperone capacity in the cytosol of aged hepatocytes	Functional changes associated with aging
HSF-1	Low levels in aged fibroblasts in culture and from the elderly	Senescence-associated quantitative and functional changes

Abbreviations: PTM, posttranslational modification; RMHS, repeated mild heat shock; HSF, heat shock factor (a regulator of transcription of heat shock genes in eukaryotes).

Table 3 Examples of disease-associated chaperonopathies^a

<i>Hsp/chaperone</i>	<i>Experimental-clinical observation</i>	<i>Disease</i>
Alpha-B-crystallin	High in IBM muscle fibers	IBM
Alpha-B-crystallin	High in glial inclusions	Tauopathies (CBD, PSP, FTDP-17)
Hsp25	Decreased in motoneurons	ALS (mouse model)
Alpha-B-crystallin, Hdj1, Hdj2, Hsp70, alpha and beta SGT proteins	Low in brain	Huntington's
Hsp72	High in plaques and tangles, and in brain cortex	Alzheimer's
Grp78	High in neurons that are otherwise normal	Alzheimer's
Hsp60, Hsp70RY, Hsc70, alpha-B-crystallin, Grp75, Grp94	Altered distribution pattern in several regions of the brain	Alzheimer's

^aFor source of data, explanations, and references, see Macario, A. J. L. and Conway de Macario, E. (2005). Sick chaperones, cellular stress, and disease. *New England Journal of Medicine* **353**, 1489–1501.

Abbreviations: IBM, inclusion body myositis; CBD, corticobasal degeneration; PSP, progressive supranuclear palsy; FTDP-17, fronto-temporal dementia with parkinsonism linked to chromosome 17; ALS, amyotrophic lateral sclerosis; SGT, small glutamine-rich tetra-trycptide repeat containing (protein).

and functionally deficient due to a defect in one of the components, e.g., a chaperone or cochaperone molecule; (4) a cell, tissue, or organ abnormality that is the consequence of the chaperone deficiency; and (5) developmental and clinical manifestations, i.e., the phenotype.

Acquired chaperonopathies are those that are not heritable; they feature defects, quantitative or structural, in the chaperone molecule due to posttranscriptional aberrations. Acquired chaperonopathies can be described at various levels, as for the genetic chaperonopathies, except that in the acquired conditions the DNA (locus, gene, exon) does not carry hereditary defects.

The chaperones discussed in this article are proteins; hence, the chaperonopathies can be considered a subset of the proteinopathies. In these conditions, a

protein is structurally and functionally altered, and it usually has a tendency to misfold, aggregate, and precipitate. Abnormal chaperones can also follow this fate.

Molecular Pathology

Structural defects, genetic or acquired, in a chaperone molecule may affect one or more of the chaperone's functional domains and may have an impact on one or more of its functions.

A chaperone molecule must be able to recognize the client polypeptide in need of assistance for folding or refolding, and it must also be able to interact with the other members of the chaperone complex (the actual chaperoning machine). Furthermore, a chaperone must be able to interact with other chaperoning

machines and with protein-degrading machines (to build the chaperone networks involved in protein quality control). Interaction with protein-degrading machines is necessary when the client polypeptide cannot be folded properly and has to be eliminated. Chaperone complex formation and networking involve distinct segments (molecular domains) of the chaperone molecule. If one of these segments is altered because of a mutation or a posttranslational modification, the particular interaction in which the affected segment is involved will not occur, will be ineffective, or will proceed at a slower than normal rate. This perturbation will affect the functioning of the entire molecule, and also the structure and function of the whole chaperone complex and network of which the affected molecule is part. As the chaperone complex is affected, so will all of those cellular processes that require the complex; pathology will ensue.

Impact of Defective Chaperones

Figure 1 shows the life history of a typical protein molecule, from the production of the message (transcription of its parent gene) encoding the amino acid sequence to its final functional form. The figure also shows the points of impact of cell stressors along the way from transcription to the final native conformation, including migration and translocation to the cell locale in which the mature protein molecule resides and functions, and the consequences of misfolding, aggregation, and deficient structure, which lead to degradation.

Deficient chaperones can cause pathological disorders of various severities in any cell, tissue, or organism, whether animal or plant. They can also affect prokaryotic cells, rendering them vulnerable to environmental changes and other agents.

Examples of Chaperonopathies

Examples of genetic, structural chaperonopathies and of polymorphisms of human chaperone genes are listed in **Table 1**. Chaperonopathies associated with senescence and with disease are listed in **Tables 2** and **3**, respectively.

Miscellaneous Lesser Chemical Warfare Agents

Glossary

<i>Acetylcholinesterase</i>	An enzyme found in the blood and at nerve endings that catalyzes the hydrolysis of acetylcholine.
<i>Blister agent</i>	A chemical compound that burns the eyes, lungs, and skin and typically forms blisters on the skin.
<i>Blood agent</i>	A chemical, typically containing a cyanide group, that prevents the normal utilization of oxygen by tissue.
<i>Chemical warfare</i>	Intentional use of chemicals, typically poisons, contaminants, or irritants, in order to kill, injure, or incapacitate.
<i>Choking agent</i>	A chemical agent that prevents normal breathing and causes a victim to suffocate.
<i>Lachrymation</i>	Excessive secretion of tears.
<i>Miosis</i>	Contraction of the pupil of the eye in response to increased light or to certain chemicals or pathological conditions.
<i>Nerve agent</i>	A chemical agent that inhibits the enzyme acetylcholinesterase and prevents the transmission of nerve impulses.
<i>Toxic industrial chemical</i>	Chemicals from industrial processes that may be hazardous to individuals.
<i>Vesicant</i>	A chemical compound that burns the eyes, lungs, and skin and typically forms blisters on the skin.

Use of Chemical Weapons

World War I was the beginning of large-scale chemical warfare. The Germans first used chlorine and phosgene gas released from gas cylinders and artillery shells; 85% of all deaths resulting from exposure to chemical warfare agents during World War I were caused by phosgene. The first use of sulfur mustard was also by the Germans during World War I. Sulfur mustard was such an effective chemical warfare agent

that it became known as the king of the battle gases. The Germans began designing a second generation of chemical weapons, the nerve agents, before World War II. Although they were never used, the Germans maintained large stockpiles of the nerve agents tabun and sarin. After World War II, the British synthesized the very potent nerve agent VX.

Even after World War II, chemical warfare agents were still in use. During the 1960s, mustard agents, riot control agents, and perhaps nerve agents were used by Egypt during the Yemen War. Iraq used sulfur mustard, tabun, and soman during the war with Iran, and it is believed that they may have used cyanide against the Kurds. There is some speculation that Iraq used chemical weapons during the first Persian Gulf War (this being the cause of Gulf War Syndrome). Many veterans of this war complain of a number of symptoms, including recurrent headaches, joint stiffness, nausea, anxiety, and depression. No conclusion has been drawn on the cause of Gulf War Syndrome, but many conclude that multiple chemical exposure, contact with pesticides, negative reactions to vaccines or side effects of chemicals given to protect against nerve agent exposure may have caused some symptoms.

Terrorist groups are now the biggest threat for using chemical weapons. Sarin was used by the Aum Shinrikyo cult in Japan in the mid-1990s. It was first used in Matsumoto in 1994 and killed seven and injured over 600. The second occurrence was in the Tokyo subway in 1995, which killed 12 people and injured more than 5000. This cult had also used VX for the assassination of important political leaders.

Chemical warfare presents a number of unique physical and psychological stresses to an individual. Military personnel not only risk the physical stress and damage caused by contact with chemical warfare agents, but also cope with the severe psychological stress that comes with the fear of risk of exposure. Wartime already presents significant fear and confusion for a soldier, and the threat of chemical warfare exacerbates this. The first responders who must respond to chemical warfare incidences also experience significant stress caused by the need to wear cumbersome protective gear, the potential accidental exposure to the chemical warfare agent, and the obligation to help the injured, dying, or dead.

For those living with the dread of war or terrorism, the stress, fear and worries can lead to severe anxiety and have a serious impact on normal life. People's mood, cognition, and behavior may be disrupted as

a result of the fear, uncertainty, and panic that may accompany a chemical warfare incident, a training drill, or a hoax. In fact, the psychological stress itself may mimic many of the physiological effects caused by exposure to chemical weapons.

Classification of Chemical Weapons

A variety of chemicals exist that may be used as chemical warfare agents. Those considered to be the biggest threat for the modern soldier are the nerve gases and mustard gases. These agents are actually liquids at ambient temperatures and are generally aerosolized in order to be efficiently dispersed. The low volatility of these agents allows them to persist in the environment for a long period of time. It is the persistence of these agents that poses a great risk for first responders and health-care workers. Other toxic chemicals such as cyanide, chlorine, and phosgene are true gases at ambient conditions and rapidly dissipate from the environment, making them less of a long-term hazard. However, some of these gases are heavier than air and may remain in low-lying areas for extended periods.

Chemical warfare agents may also include riot control agents, such as tear gas and pepper sprays, and even herbicides. Agent Orange was a herbicide used during the Vietnam War to remove foliage and expose hidden enemy soldiers. With the growing fears of terrorism, two of the largest classes of chemicals of concern are the toxic industrial chemicals (TICs) and toxic industrial materials (TIMs). If a terrorist organization were to release any of these chemicals into the environment, the impact would be devastating.

Vesicants

The vesicants are a broad class of chemical agents that produce vesicles or blisters on the skin and the mucous membranes. These chemicals include sulfur mustard, the nitrogen mustards, Lewisite, and phosgene oxime.

Sulfur mustard was developed by Germany before World War I and was noted to smell like mustard and taste like garlic. Pure sulfur mustard is known as HD; it is a strong alkylating agent, known for its ability to react with a number of biomolecules, including proteins, DNA, and RNA. The organs most commonly affected by mustards are the skin, eyes, and those in the respiratory system. Sulfur mustard does not have an effect at first contact, and a dose-dependent latent period exists before effects begin to occur. Nausea and burning of the eyes are often the first

symptoms of mustard exposure. Blistering and itching of the skin, chest pains, coughing, lesions, or blindness may begin to occur within a few hours or days after exposure. There is a poor understanding of exactly how mustard produces blisters. Most symptoms begin to heal within few weeks of exposure; however, neurosis, depression, and continuous eye problems have been noted as long-term effects. Of the soldiers exposed to mustard gas during World War I, only 3–4% died of its direct effects. Death typically occurs due to secondary infections, shock, or respiratory insufficiency. There also exists some data that suggest that chronic exposure to mustard may increase the likelihood of developing cancer of the mouth, throat, and respiratory tract.

The nitrogen mustards, referred to as HN1, HN2, and HN3, are also potent vesicants. Although the nitrogen mustards are structurally similar to the sulfur mustards and have common chemical reactions, they have never found use as weapons. They produce damage to the eyes, respiratory tract, and skin similar to sulfur mustard; however, onset may take place more rapidly. Nitrogen mustard (HN2) was manufactured and used for a number of years in chemotherapy.

Lewisite was developed during World War I to be less persistent than mustard since waging an attack on mustard-containing areas was difficult. Lewisite was never used in war. The toxic effects of Lewisite are similar to those of sulfur mustard; however, the onset of effects occurs within seconds of exposure. Like other vesicants, Lewisite is a potent inhibitor of enzymes, inhibiting via the interaction of the Lewisite arsenic group with enzyme cysteine residues. Like sulfur mustard, the exact mechanism of toxicity is poorly understood.

Nerve Agents

The nerve agents are a class of organophosphorous esters, similar to pesticides, that are rapidly lethal via any route of exposure. There are two major classes of nerve agents: V and G. The G series agents include tabun (GA), sarin (GB), soman (GD), and GF. The V series agents include VX and Russian VX. The relative toxicity of the nerve agents is $VX > GD \sim GF > GB > GA$. The nerve agents are about 1000 times more potent than the most potent commercially available pesticides. VX is especially potent since it has a low volatility, making it a serious contact threat, and it is stable in the environment. The G series agents are more volatile and do not pose as much of a contact hazard.

The nerve agents act by irreversibly binding to esterase enzymes, especially acetylcholine esterase, which is present in the blood and at the neuromuscular junctions in the peripheral and central nervous systems. The binding of nerve agents to acetylcholine esterase causes inhibition of the enzyme and leads to an accumulation of acetylcholine. The clinical effects of nerve agents are due to the build-up of acetylcholine within the nervous system, which, depending on dose and route of exposure, may lead to a variety of symptoms, including miosis, nausea, tightness in the chest, vomiting, increased sweating and salivation, lachrymation, headaches, weakness, twitching, muscular and abdominal cramps, diarrhea, blurring of vision, anxiety, and tremors. Death can occur through respiratory arrest or cardiac arrhythmia. Severe poisoning by nerve agents may cause long-term physiological, psychological, and neurological effects such as cerebral impairment and cardiac malfunctioning as well as posttraumatic stress disorder and differences in intellectual and motor skills. Exposure to small concentrations of nerve agents may cause depression, forgetfulness, inability to concentrate, bad dreams, insomnia, and irritability.

Miscellaneous Lesser Chemical Warfare Agents

The cyanides, often referred to as blood agents, were used as chemical weapons during World War I by the French and Austrians. Cyanides have also reportedly been used during the Iran-Iraq War. The cyanide gases are difficult to deliver since they rapidly disperse into the environment due to their high volatility. There are three main types of cyanide: hydrogen cyanide (AC), cyanogen chloride (CK), and cyanogen bromide. The cyanogen halides (cyanogen bromide and cyanogen chloride) react in the body to produce hydrogen cyanide and hence have a very similar toxic effect. The target of cyanide toxicity is cellular respiration in the mitochondria. The cyanide ion reversibly inhibits cytochrome oxidase, which is the terminal oxidase in the mitochondrial respiratory chain. Inhibition leads to tissue asphyxia, resulting in central respiratory arrest and death. In addition, cyanogen chloride and cyanogen bromide act as irritants and may cause ocular and respiratory tract irritation. Recovery from cyanide poisoning, if it is not fatal, is typically rapid.

Phosgene and chlorine comprise a class of chemical gases called pulmonary agents (also referred to as choking agents) since they cause severe lung irritation that leads to fluid accumulation in the lungs (pulmonary edema), which can choke the victim. Phosgene

injury is caused by hydrochloric acid that is formed in the lungs and by diamide formation that cross-links cellular components. Chlorine (often referred to as CL) and phosgene (designated CG) were used during World War I. Phosgene accounted for 85% of all World War I deaths caused by chemical weapons. The risk of use of chlorine and phosgene remains high since they are used extensively in industry, making them readily available for use by terrorist groups.

Riot control agents, most commonly referred to as tear gases, are nonlethal compounds used to temporarily disable individuals by irritating exposed mucous membranes and skin. Most tear gases are effective within seconds to minutes, but their duration of effect is brief once an individual has been removed from exposure. Common riot control agents include chloroacetophenone (CN), the active ingredient in Chemical Mace, and *o*-chlorobenzilidene malonitrile (CS). These chemicals are ideal for use as riot control agents since the dose required to be effective is significantly lower than the lethal dose. These agents are typically aerosolized or released as smoke, and they cause burning irritation in the eyes, lachrymation (tear production), chest tightness, cough, sneezing, and a burning sensation of the skin. Oleoresin capsicum (OC), commonly referred to as pepper spray, is also considered a riot control agent.

Incapacitating agents are anticholinergic compounds that affect the central nervous system. These include the compound 3-quinuclidinyl benzilate (BZ) and also lysergic acid diethylamide (LSD). Those exposed to incapacitating agents suffer from drowsiness, poor coordination, slowed thought processes, and delirium. Hallucination may also be experienced. These effects can last from a few hours to a number of days. The Bosnian Serbs were alleged to have used BZ against civilians.

Biological toxins are sometimes referred to as chemical weapons since they are not living organisms. Many biological toxins mimic a number of chemical weapons. For example, the effects of capsaicin (from the oil of hot peppers) mimic those of artificially manufactured lachrymators. Other toxins include botulinum toxin, ricin, and mycotoxins. Botulinum toxin may cause paralysis and death and is about 15 000 times more potent than VX. Ricin is a plant toxin that is easily produced from castor beans and inhibits protein synthesis in the ribosome. Botulinum toxin and ricin have been used to perform assassinations. Tricothecene mycotoxins are produced by molds. Exposure to mycotoxins resembles exposure to vesicants. Soviet-supported forces have been alleged to use tricothecene mycotoxins in aerosolized droplets

against Afghanistan, Laos, and Kampuchea. They may have also been used during the Iran-Iraq war.

Although not commonly referred to as a chemical warfare agent (since it was not specifically used to cause direct harm to individuals), the herbicide Agent Orange was used extensively in Vietnam to remove foliage and expose enemy soldiers. Agent Orange is a mixture containing the phenoxyacetates 2,4-D and 2,4,5-T; some preparations contained tetrachlorodibenzodioxin (TCDD). TCDD is a dioxin that may be a carcinogen and a teratogen. Following the Vietnam War, veterans began to report a number of health problems, including skin rashes, cancer, psychological symptoms, birth defects, and handicaps in their children. Agent Orange may affect the nervous system causing psychiatric illnesses and problems with the nerves responsible for movement and sensation.

Finally, there is a growing fear that terrorist organizations will move away from the more traditional chemical warfare agents and begin using so-called agents of opportunity. These include a number of common and not-so-common industrial chemicals, TICs and TIMs. Examples include chlorine, ammonia, formaldehyde, fluorine, and sulfur dioxide. These are chemicals that are commonly used in industrial processes, relatively available, easy to disperse, and significantly toxic. Release from a chemical plant could produce a large plume, threatening nearby communities. Also, a truck carrying these chemicals could easily be hijacked and its contents released in a highly populated area. It is this ease of availability

that potentially makes TICs and TIMs more ideal than traditional chemical warfare agents for use as a terrorist's weapon.

The Chernobyl Accident: Health Consequences

Short-Term Stress Effects

Long-Term Stress Effects

Short- and Long-Term Stress Effects in Far-Off Areas

Glossary

*Acute radiation
syndrome
(ARS)*

ARS is the collective term for the hematopoietic, gastrointestinal, and central nervous system/cardiovascular systems response to whole-body acute or subacute exposure to penetrating ionizing radiation (e.g. x-ray or gamma radiation) above a certain threshold (roughly 1–2 Gy).

The study of the causes of disease.

Etiology

Pathogenesis

The origin and development of disease.

Shock trauma

A severe psychological experience, usually involving a threat to life, for which the individual was totally unprepared.

<i>Thyroid gland</i>	An endocrine gland, which is located in the base of the neck and produces thyroxine.
<i>United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR)</i>	UNSCEAR mandate in the United Nations system is to assess and report levels and effects of exposure to ionizing radiation and the Committee was established by the General Assembly of the United Nations in 1955. Governments all over the world rely on the Committee's estimates as the scientific basis for evaluating radiation risk and for establishing protective measures.

The Chernobyl Accident: Health Consequences

The nuclear reactor accident in Chernobyl, Ukraine, on April 26, 1986, created acute, short-term, and long-term effects both locally and farther away. The Chernobyl nuclear power plant (NPP) is located in the Kiev region of Ukraine, 15 km from the southern border of the Gomel region of Belarus and 150 km from the western part of the Bryansk region in Russia.

In contrast to the Three Mile Island accident in 1979, in which the safety containment held the release, at Chernobyl there were extremely large releases of radioactivity to the environment because the design of the reactor did not provide for the additional safety containment. Furthermore, it is unlikely that containment could have withstood the kind of pressure that the Chernobyl accident created. The graphite used for moderating the RBMK reactor kept a fire and the releases going for approximately 10 days, and it led to substantial cross-border radioactive fallout. The radioactive fallout resulted in three main spots of contamination within the former Soviet Union; they have been termed the Central, the Bryansk-Belarus, and the Kaluga-Tula-Orel spot.

The far-field fallout was chiefly dependent on the meteorological conditions; these affected the direction taken by the atmospheric releases and whether precipitation occurred while the release passed a particular area. The radioactive clouds first spread to Scandinavia and then turned toward the Balkans, affecting various other parts of Europe. It is important to note that the washout from the Chernobyl fallout plume resulted in very heterogeneous fallout, especially compared to previous experiences with atomic bomb test fallout. Although, the levels of bomb fallout had also been associated with washout and precipitation levels, they were not associated with such extreme local variations as observed with the Chernobyl fallout. The previous experiences with more homogenous bomb fallout made quite a few

experts believe that the early measurements from a few areas were valid indications for larger areas. However, with such a patchy fallout pattern, this was not the case. For instance, in Norway when the central Oslo area was not affected with fallout, experts made conclusions about the rest of the country that later turned out to be premature. UNSCEAR has estimated that 57% of the collective effective dose was received in Europe, outside the former USSR.

To avoid deterministic health effects from exposure to ionizing radiation, the city of Pripjat (49 000 inhabitants) located 3 km from the Chernobyl NPP was evacuated by Soviet authorities on Sunday, April 27. However, until the evacuation was ordered, the inhabitants of the town were given no official information about the accident and, for instance, the amusement park was open on Saturday evening. In fact, the official news report in the mass media of the Chernobyl accident started on Monday, April 28 as a local incident at the Swedish NPP Forsmark; as an employee entered the NPP, he triggered the alarm system because of Chernobyl fallout on his foot. The Forsmark NPP dispatched emergency measurement crews, which found increased radiation levels everywhere; hence, the Forsmark NPP was evacuated. On Monday, Swedish and Finnish authorities exchanged measurement data and pressed the Soviet authorities in the evening to communicate to the world that there had been an accident.

Because of the information blockage by Soviet authorities, the trust – and lack of trust – in the available information was a central issue. Also, within the same power structure held by the Soviet state, gigantic clean-up and intervention measures were conducted, some of which might have a quite limited dose-reduction effect compared to their rather large negative psychosocial effects.

On May 2 and 3, an additional 11 000 inhabitants in 14 villages in the 10-km zone were evacuated, and 42 000 inhabitants of 83 villages within the 30-km zone were evacuated between May 4 and 7. Furthermore from June to September, an additional 57 villages in Belarus, one village in Ukraine, and four villages in Russia (Bryansk region) were resettled, resulting in a total of 116 000 evacuated individuals. There is an ongoing discussion about whether the health gains from reducing the exposure to ionizing radiation by the ordered evacuations of all these people outweighed the psychosocial and stress impacts of being evacuated.

Extensive research on the health effects of the two major civilian nuclear reactor accidents (Three Mile Island and Chernobyl) has pointed to one particular finding that is considered to be of major importance, namely the impact of the psychological

fallout. Psychological impacts are important not only after the event of a nuclear accident itself but also with regard to the threat of a nuclear accident, the threat of nuclear material gone astray, or, with the war on terror, the threat of a terrorist event involving radioactive material.

Before we return to these psychological effects, a description of the more immediate and somatic effects is given.

On-Site Consequences

During the night of April 25–26, 1986, 176 staff members were working the night shift on Units 1–4 of the Chernobyl NPP while 268 staff members were working night shift on constructing two new additional reactors some 1.5 km to the southeast of the other reactors. A plant employee working immediately above the exploding reactor was killed instantly. His body could not be recovered. Another employee was crushed by debris and badly burned, and he died from his injuries within hours.

Those participating in the heroic immediate firefighting efforts were the most heavily affected by exposure to ionizing radiation immediately after the accident. More than 100 firefighters from the plant and from the nearby city of Pripyat participated in the vital task of limiting the raging fires and saving the other reactors also from exploding; around 5:00 a.m., all fires except the graphite fire in the core were extinguished. The heroic efforts of the firefighters, emergency workers, and plant personnel were vital in limiting the consequences. These efforts caused these workers to experience many injuries and exposure to much ionizing radiation, but saved reactor Unit 3 of the NPP (without their efforts a hydrogen fire or explosion and fire in the oil of the turbines might have had even larger consequences).

An explosion in the core of the reactor had not been thought to be possible. In harmony with human behavior in other crisis situations, hours passed until the operating crew of Unit 4 accepted and realized the consequences of the reports from the rescue workers that the core had been destroyed. The denial of these observations led to a delay in their realizing that highly dangerous graphite and other debris from the core were causing the fires on the roofs (including the roof of Unit 3). Radiation levels were so high in the damaged part of the plant and outside that the monitoring equipment could not measure it – the readings went completely off scale. The firemen and the plant personnel had no personal dosimeters and were very severely exposed. Within 1 h, the first of many cases of acute radiation syndrome (ARS)

appeared, during the first 12 h 132 emergency workers were hospitalized in Pripyat, suspected to be suffering from ARS. On Saturday, a specialized emergency team was established and examined some 350 people within the first 3 days, identifying 299 suspected cases of ARS.

Those with indications of ARS were sent mainly for specialized treatment to Moscow and to hospitals in Kiev. During the subsequent days, some 200 people were admitted for examination. The specialized treatment center in Moscow admitted the more severe cases, and after screening, it treated 115 patients for ARS. These patients were categorized into four categories according to the severity of the ARS. All the 20 patients with fourth-degree ARS (bone marrow dose range 6.1–16 Gy) died; 14 of the 21 patients with third-degree ARS (bone marrow dose range 4.2–6.4 Gy) survived; 42 out of the 43 with second-degree ARS survived; and all 31 with first-degree ARS survived.

After extensive effort, the Moscow center managed to establish that the two most significant dose factors were that of a general relatively uniform whole-body gamma irradiation and extensive beta irradiation of extensive body surfaces. The beta-radiation burns caused extensive skin lesions that proved to be a significant problem, and 16 out of the 28 deaths have skin injuries listed along with other causes of death. All in all, there were a total of 32 deaths during the initial period.

There is an ongoing controversy regarding the number of deaths among the 600 000 liquidators, with many heterogeneous subgroups including the early-involved firefighters and the soldiers who removed debris and built the sarcophagus over the wrecked reactor.

Far-Field Effects

One of the somatic health impacts of Chernobyl that is currently demonstrated is the large increase in the prevalence of thyroid diseases, including cancer, in children in the affected areas in the former Soviet Union, mainly in Belarus and Ukraine. In Belarus, Ukraine, and Russia, 5 million people were exposed to low levels of ionizing radiation over an extended period of time. It has been important, but difficult, to make a clear distinction between the immediate and deferred direct effects arising from exposure to radiation and the possible indirect psychosomatic effects. Complex psychosomatic or somatopsychological processes may be at work. People in the affected areas naturally feared that they had been exposed to radiation that might cause future health damage.

The political strategy of the Soviet experts and authorities in the management of the postaccident

situation involved, first, the withholding of information from the population by creating a total information blockade and, second, the psychiatrization (blaming the victim) of the health consequences of the accident. For example, the term radiophobia was widely used starting in 1986 to explain the population's reactions, despite the objective evidence of there being valid reasons for a certain degree of fear.

Short-Term Stress Effects

The explosion in the NPP contained stressful stimuli typical of shock trauma. This is likely to produce acute stress reactions and later posttraumatic stress disorder (PTSD, a psychiatric disorder characterized by intrusive recollections and the reliving of the trauma, along with symptoms of avoidance and hyperarousal. Unlike the stimuli carrying a high risk of PTSD, which were time-limited dangers, additional stressors inherent in the radioactive contamination were ongoing, future oriented, somatically based, and not confined to a single past event that could be processed by the senses.

The Chernobyl NPP accident started a sequence of events that has continued to unfold over several years, thereby creating a situation of chronic stress. For the people exposed, the Chernobyl nuclear accident had no clearly defined low point from which things would gradually get better. Exposures to a high-risk environment, even when the feared consequences, such as cancer, may never materialize, elicit stress reactions that are influenced by individual perceptions of the danger. The fear was aggravated by the lack of adequate information immediately after the accident.

Human contamination of the biosphere is a comparatively new type of crisis. Rather than merely an ecological and medical emergency, this was also a social and political crisis. In the affected regions, covering thousands of square kilometers, a culture of uncertainty developed. The environmental contamination was not possible to see, hear, smell, taste, or touch. In a silent disaster, it is impossible for humans to determine if and when they are being exposed because they are totally dependent on experts for information. Because of the secretiveness of the Soviet authorities, news about the accident was released several days after the accident. Only then did the populations in nearby towns become aware of the radiation to which they had been exposed and the consequent threat of long-term illness. These people were struck by fear and the distrust of political authorities. When people were evacuated from their homes, they suffered considerable stress because they were kept ignorant about what was going on. They underwent disruption in

community infrastructure and social interaction and faced uncertainty about future housing and employment. Many evacuees who moved to new settlements were particularly depressed in their new homes because of financial difficulties, fear of isolation, and concern for the health of their children. The tense situation caused considerable stress, which, combined with the constant fear of health damage from the radioactive fallout, led to a rising number of health disorders being reported to local outpatient clinics. People received late and reluctant information, leading to widespread rumors. Only 30 months after the accident did Soviet authorities admit the contamination of some villages. This obvious disinformation resulted in widespread indifference, denial of danger, and public distrust in the government. People suffered from various symptoms frequently called chronic radiation sickness, the exact definition of which varied; fatigue, loss of memory, loss of appetite, and psychosomatic symptoms were among the most frequently documented symptoms in the clinics.

The findings of increased somatic complaints, with large discrepancies between the findings of thorough clinical examinations and the self-reports is reminiscent of Lifton's psychosomatic bind, found among Hiroshima atomic bomb survivors. Thus, substantial proportions of the populations in the former Soviet Union, severely affected with Chernobyl fallout, live with an intense focus turned inward, listening for all kinds of physical health complaints that might possibly be the first signals confirming their expectations of becoming ill consequent to the impact of Chernobyl.

Similarly, in recent years, several authors have suggested that psychological factors may be involved in the etiology and pathogenesis of the health problems occurring after toxic exposure. A number of terms have been proposed to describe this syndrome: chronic environmental stress syndrome, informed of radioactive contamination syndrome, and toxic stress syndrome.

Long-Term Stress Effects

The breakup of the Soviet Union in 1989 increased the level of stress in the affected populations dramatically. Added to the ecological crisis, the chronic political, economic, military, social, and psychological crisis introduced a cluster of stressors for ordinary men and women. Insecurity, unpredictability, and shortages in goods and other life necessities caused severe hardships. Within this total situation of need, the relative importance of the Chernobyl problem was reduced. The numerous health problems reported by the local population of all ages are, however,

attributed to the radioactivity. Even the fall of the Soviet Union has been attributed to the Chernobyl accident. However, problems in everyday life are so demanding that many people cannot muster the necessary energy to maintain adequate precautions concerning radioactive contamination. Thus, attribution and indifference appear to be common stress reactions. Studies by Johan Havenaar and colleagues, in particular, in the affected regions have shown that the psychological impact of exposure to noxious agent has induced a wide range of health effects, including symptoms of anxiety; depression; non-specific somatic complaints, especially fatigue and headaches; loss of concentration; subclinical physiological changes; increased illness awareness; lowered threshold for illness roles; and increased help-seeking behaviors.

Evelyn Bromet and colleagues have shown how mothers with small children are a vulnerable group both after the Three Mile Island and the Chernobyl accident, and seemingly their immediate coping is important also for the long-term impacts.

Short- and Long-Term Stress Effects in Far-Off Areas

Paradoxically, people in remote areas – as far away as Norway and Sweden – were alarmed at a fairly early stage due to nuclear monitoring and Western news media. These countries received heavy fallout due to the unfortunate wind direction and rain. Reactions varied among public awareness, alarm, and shock. Studies have shown that an information crisis developed in the first weeks following the Chernobyl disaster. The information crisis resulted from a combination of factors: (1) the shortcomings of previous public education on the matter; (2) the shortage of reliable data on the location and concentration of radioactive material, including the premature, too optimistic expert conclusions erroneously taking the central-location measurements to be indicative of the whole country; (3) the diffuse threat, ambiguous risk, and theoretical complexity of the subject; (4) the seeming contradiction between the health authorities' assurances that, on the one hand, the radiation level was not dangerously high and, on the other hand, some precautions had to be taken; (5) the experts' obvious difficulties in conveying simple information on complicated matters and statistical risks; and (6) the media's focusing on conflicts, particularly between experts.

In Scandinavia, it was found that, although the majority of the population was psychologically affected by the crisis in that all but few had some reactions to it, only a small proportion (1–3%) seemed to

have developed posttraumatic stress reactions of such a severity that they needed or sought help. Data analysis showed that the degree of exposure, sex, age, educational level, general threat perception, and previous mental health were associated both with information and with the reaction variables. Women were significantly more alarmed than men.

The Southern Saamis was the group that was worst affected in Scandinavia because radiocesium from Chernobyl fallout went into the Lichen (reindeer) Saami food chain. The Southern Saami reported that repeated whole-body measurements aided them in turning to a more active coping style in which they believe there indeed is something they might do – the application of countermeasures to influence possible adverse health effects. This is in stark contrast to some of the more fatalistic coping patterns found among the populations in many contaminated places in the territories of the former Soviet Union.

Providing the public with immediate, simple, and reliable information is of crucial importance in the management of such silent disasters. In fact, in such disasters, information can itself be a threat. It is not realistic for the relevant authorities to start producing information materials or to start educating the public during the height of a crisis; thus, it is important that preparatory efforts be made. A key issue for the public is what people themselves might do to influence the possible health impacts on themselves and their family in case of an accident, and this perspective should be center stage for authorities charged with the challenging task of providing information.

Child Physical Abuse
Child Neglect

Glossary

<i>Factitious disorder by proxy</i>	Disorder that occurs when adults deliberately produce or feign physical or psychological symptoms in a child under their care with the presumed motivation a psychological need to assume the sick role.
<i>Failure to thrive</i>	In infancy this is indicated by a growth delay with postural signs (poor muscle tone, persistence of infantile postures) and behavioral signs (unresponsive, minimal smiling, few vocalizations) and may be a result of child neglect.
<i>Multisystemic therapy for child abuse and neglect (MST-CAN)</i>	An ecological treatment model that takes into account all of the etiological factors related to a problem behavior and treats those factors through changes in the family and social ecology. The delivery of treatment is generally in the home and at times convenient for

families, with 24 hours a day, 7 days a week on-call coverage for crises. This treatment is an adaptation of standard MST that has established efficacy with deep-end delinquents. MST-CAN, developed at the Medical University of South Carolina, has been shown to be effective with physically abused children and their families.

Parent-child interaction therapy (PCIT)

A short-term early intervention approach in which young children and their parents are provided with direct coaching in interactions during play or specific tasks. PCIT is appropriate for young children demonstrating externalizing and internalizing behavior problems. PCIT has recently been established as effective with physically abused children and their families in a clinical trial at the University of Oklahoma Health Sciences Center.

Reinforcement-based intensive outpatient therapy (RBT)

A treatment model developed at Johns Hopkins University and applied to mothers with heroin or cocaine addiction. The model provides intensive treatment and focuses on skills needed to become abstinent, monitoring of substance use, abstinence-contingent housing, prosocial recreational activities, social skills, and employment counseling.

Shaken baby syndrome

An injury to the brain of an infant that results from vigorous shaking. Shaken baby syndrome is a form of physical abuse and often results in death to the child.

Child Physical Abuse

Child physical abuse is defined as physical injury to a child under age 18 by an adult. Acts of physical abuse may vary from hitting that leaves bruising to actions that involve welts, cuts, bites, broken bones, burns, poisoning, and internal injuries to soft tissue and organs. In special cases, termed factitious disorder by proxy, adults inflict injury or induce illness in a child under their care, present the child for medical care, and feign no knowledge of the etiology.

Epidemiology

According to reports from state agencies, nearly 3 million children are abused and neglected annually. Among those reported for suspicions of abuse, roughly 25% are investigated for physical abuse. In a congressionally mandated prevalence study of child abuse and neglect called the Third National Incidence Study, a broader sample of cases that extended beyond child protection reports was included. Of the 2 815 600 abused or neglected youth, 22% were physically abused.

Etiology

The complexity of child abuse and neglect is highlighted in the literature, showing that multiple risk factors relate to whether physical abuse will occur. These risk factors include (1) parent factors such as history of abuse, substance abuse, deficits in knowledge of child development, depression, poor impulse control, negative perception of the child, and neuropsychological dysfunction; (2) child factors such as age, aggression, noncompliance, and delayed development; (3) family factors such as high conflict, spouse or partner abuse, and single marital status; (4) social network factors such as social isolation, low use of community resources, and limited involvement in community activities; and (5) community factors such as economic disadvantage, instability, poor organization, and high resource need coupled with low resources available for child care. Although each of the systems noted above (i.e. family, community) is part of every child's life, the particular risk factors within each system will differ from family to family. For example, in one family, substance abuse, child aggression, and isolation from social networks may be the key factors driving the abuse. In another family, partner violence, child developmental delay, living in an unstable neighborhood, and low parenting skills may be the driving risk factors.

Medical and Mental Health Effects

Physical abuse injuries range from mild (e.g., bruises) to severe (e.g., broken bones, gunshot wound) and

account for 10% of injuries among children who present for emergency room care. Physical injuries that might be mild for an older child can be fatal for an infant. For example, when babies are shaken, the resulting damage to the brain can leave children severely developmentally delayed but may also result in death. This act against infants is termed shaken baby syndrome. Some children do not need medical care following physical abuse, but an assessment of potential injury is always a safe bet. Mental health effects of child physical abuse vary by the child, experience, and context of the abuse. These effects generally occur in five domains: (1) aggression and behavioral dysfunction toward peers and adults; (2) poor interpersonal relations and social competence such as social skills deficits, poor social problem solving, and peer rejection; (3) trauma-related emotional symptoms such as depression, posttraumatic stress disorder (PTSD), anxiety, and suicidality; (4) developmental deficits in relationship skills including anxious attachment in very young children, low frustration tolerance, and difficulty managing conflict; and, (5) cognitive and neuropsychological impairment such as receptive and expressive language difficulties and low performance in math and reading. In addition, physical abuse places children at risk of long-term mental health difficulties in adulthood such as substance abuse, violent crime, depression, and relationship problems.

Treatment Approaches

In a number of practice settings, physically abused children participate in individual treatment and parents go to parenting groups. The literature on physical abuse indicates that behavioral parent training has empirical support with this population for reducing parental aggression toward children. However, the problem of child abuse and neglect is so complex that individual child treatment or parent training alone will not resolve the risk factors that have led to the abuse in the first place. Since 1996, advances have been made in research regarding the treatment of physically abused children and their families. Through randomized clinical trials, three treatments are showing promise: parent-child interaction therapy (PCIT), trauma-focused cognitive-behavioral therapy (CBT), and multisystemic therapy for child abuse and neglect (MST-CAN). All three are treatments that address parent and child risk factors. This characteristic is important in that past research has focused on treatment of the parent or child only. Given the multidetermined etiology that relates to physical abuse, the importance of continued evaluation of comprehensive treatments and dissemination of effective treatments is paramount. Parental substance abuse has become a major factor in child

abuse and neglect reports and out-of-home placement. Treatments that successfully address substance abuse and child abuse are sorely needed.

Child Neglect

Despite inconsistencies in state definitions, generally neglect is defined as physical (refusal or delay in seeking health care; inadequate supervision, hygiene, nutrition, and safety), emotional (failure to provide adequate attention, warmth, and affection and/or exposure to substance abuse or violence), and/or educational (failure to promote education or school attendance and inattention to special education needs) omissions in parenting. Recent evidence suggests that these neglectful behaviors fall into three distinct categories: physical, psychological, and environmental neglect. Child neglect has been grossly underresearched in the United States, leading to the phrase neglect of neglect. Throughout the literature, child abuse and neglect often are grouped together despite the clear distinction between acts of commission and those of omission. Whereas many people think of child abuse when considering child maltreatment, child neglect is in fact more prevalent, costly, and detrimental.

Epidemiology

Of the 896 000 indicated child maltreatment cases in the United States in 2002, over 60% of those children were exposed to neglect. The number of youths who experience child neglect has more than doubled since the mid-1980s, an increase more than eight times greater than the rise in children's population. Moreover, prevalence studies suggest that approximately 45% of child maltreatment fatalities are the result of neglect, with 1 400 deaths recorded in 2002. These figures likely provide a gross underestimate of the incidence of child neglect in our country, as acts of omission are far more difficult to identify than those of commission. Studies from the general population suggest that as many as 2 million children are endangered by neglect.

Etiology

As with child physical abuse, the factors related to neglectful parenting practices are multidetermined. Evidence suggests that risk factors include (1) parent factors such as mental illness, low cognitive functioning, substance abuse, and a history of child maltreatment; (2) family factors such as domestic violence, social isolation, high levels of family stress, and poverty; (3) child factors such as child physical disability or chronic illness; and (4) community factors such

as impoverished neighborhoods, acceptance among community members of low monitoring or low school attendance, and poor community cohesion.

Although the etiology of neglectful parenting is multifaceted, of particular note is the influence of substance abuse. There appears to be an association between the staggering increase in neglectful parenting practices and the increase in identified substance abuse among child welfare cases. Children whose parents abuse substances are more than four times as likely to be neglected as those who are not abusing substances, and parental substance abuse is more often a factor in reports of child neglect than other forms of child maltreatment. Parental substance abuse, which is identified in up to 79% of child protection cases, not only is one of the strongest risk factors for abuse and neglect, but also is the deciding factor in the majority of cases in which children are taken into custody and placed out of the home.

Medical and Mental Health Effects of Child Neglect

The medical and mental health effects of neglect on the child are dependent on the nature of the neglectful parenting practices. Potential consequences are immense and can cause deleterious physiological and emotional stress on the child and family. Compared to other forms of maltreatment, child neglect has been associated with the most profound developmental and cognitive delays and has the greatest risk of enduring effects. Children who are neglected often evidence language and academic deficits, inadequate social skills, poor growth development including nonorganic failure to thrive, medical problems, and poor attachments and interpersonal relationships. Moreover, those who are neglected by substance-abusing mothers are at increased risk for conduct problems including delinquency, substance abuse, and maltreatment of their own children. The most severe forms of neglect, however, result in child fatality.

Treatment Approaches

There is a dearth of controlled clinical trials with sufficient power to examine outcomes with regard to neglect. Despite these deficits in the literature, there is evidence to suggest that an ecological approach to treatment is beneficial with neglectful families. Across studies, results suggest that neglectful parents benefit from skills training including improved problem solving, reducing safety hazards, increasing hygienic and home cleaning practices, and improving child nutrition and intellectual stimulation. Further, studies have demonstrated positive parental response to protocols targeting improving adaptive attachment styles, affective relationships, and recognition of children's

emotional needs. Despite these advances in treatment approaches with neglectful parents, there is a strong need for evidenced-based practice in this area. In particular, an urgent need exists for treatment models to address co-occurring substance abuse and child abuse and neglect. At present, the majority of treatments address the two problems independently. Work has begun in Connecticut on a project known as Building Stronger Families. This project involves the integration of MST-CAN and reinforcement-based therapy. The latter has established efficacy with serious substance abuse.

Treatment Approaches

Glossary

Child physical abuse Involves physical behavior by an adult toward a child that results in injury to the child. Signs of physical abuse may

Multisystemic therapy for child abuse and neglect (MST-CAN)

include bruises, welts, cuts, broken bones, skull fractures, burns, poisoning, internal injuries of soft tissue and organs, and injuries to the bone and tissue joints of a child under the age of 18 years

An adaptation of multisystemic therapy for delinquency that involves treatment of the entire family through interventions targeting multiple risk factors. Treatment is delivered in the home and at times convenient for families, with 24 hours a day, 7 days a week on-call coverage for crises. This model, developed at the Medical University of South Carolina, is applied to families who have come under the guidance of child protection due to physical abuse.

<i>Munchausen by proxy syndrome (MBPS)</i>	A form of child abuse in which a parent fabricates or produces illness in a child and/or creates physical signs that persistently result in unnecessary medical treatment.
<i>Parent-child interaction therapy (PCIT)</i>	A short-term intervention currently applied to young children and their parents. The method involves direct coaching of parents in interactions during play or specific tasks. Through a recent clinical trial conducted at the University of Oklahoma Health Sciences Center, PCIT was established as effective for treating young physically abused children.
<i>Shaken baby syndrome</i>	Applies to infants who undergo vigorous shaking that leads to acceleration-deceleration injuries to the brain. These infants generally present at less than 1 year of age with seizures, vomiting, lethargy or bradycardia, hypotension, respiratory irregularities, coma, or death.

Child physical abuse is a major public health problem that generally involves acts of physical violence by a parent or carer toward a child. Because physically abusive acts range greatly in intensity and duration, the subsequent mental health consequences vary widely. Treatment must involve the child, parent, and entire family.

Prevalence

Data regarding the prevalence of child physical abuse (CPA) in the United States are gathered from child protection agencies and through national surveys. These data indicate that annually, nearly 3 million children are abused and neglected. Among those reported for suspicions of abuse, roughly 25% are investigated for physical abuse. In an evaluation of reporting practices of professionals, the National Center on Child Abuse and Neglect (NCCAN) conducted a series of National Incidence Studies of Child Abuse and Neglect. They found that approximately 2.3/1000 children are physically abused. The 1995 Gallup poll estimated the rate of CPA to be 49/1000 children, more than five times the NCCAN report.

Etiology

The etiological factors related to CPA are multiple and complex. They range across many different systems (e.g., parent, child, family) and vary by individual families. Current research has not established what factors cause physical abuse. At best, the understanding of etiology involves factors that

correlate with physical abuse, also called risk factors. These risk factors are specific to the child, parent, family, and community.

The children most at risk of physical abuse are those who (1) are younger, (2) have developmental delays, (3) have other special needs such as chronic medical conditions, and (4) exhibit noncompliant behavior. A number of parent factors increase the risk of physical abuse. First is childhood abuse history. Roughly one-third of adults who were physically abused as children go on to abuse their own children. Second, certain cognitive factors increase the parent's risk of harm to the child. Parents who view their child in a negative light, distort beliefs about the reasons why children act as they do (e.g., he cries to make me upset), expect the child to be responsible for the parent's welfare, and have unrealistic expectations beyond age and skill capability are at greater risk of abusing their child. Parents who physically abuse are more likely to show emotional difficulties such as difficulty regulating emotions, including irritability, sadness, anxiety, explosiveness, hostility, anger, and perceptions that life is more stressful. They are more likely to show deficits in positive parenting. Psychiatric difficulties such as depression and posttraumatic stress disorder may make general problem solving difficult and hamper an individual's capacity to regulate emotions and parent in a nonphysical way. Parental substance abuse, in particular, is a factor that places parents at significant risk of abusing their children and is a major factor in the decision to remove children from their families and place them in state custody. Family factors that increase the risk of physical abuse include a volatile home environment in which there is domestic violence, limited psychosocial resources, and general family stressors such as frequent moves or family dissolution. Existing research has identified economic disadvantage, instability and isolation, and neighborhood burden as factors that increase the risk of child maltreatment. The latter factor, neighborhood burden, refers to greater childcare need with fewer resources.

Mental Health Effects

Mental health difficulties related to CPA include those that occur in the short term and those that persist. It should be noted that some physically abused children will not experience mental health problems. Others will experience problems that dissipate with time or with intervention, and yet others will experience problems that endure into adulthood and result in patterns of behavior and coping that disrupt the management of behavior, emotions, and relationships.

Risk and Buffering Factors

In part, the emergence and persistence of symptomatology relate to factors specific to the event, cultural and community context, family, and individual characteristics. Such factors may potentiate a negative or a buffering effect. In relationship to the event, exposure to multiple incidents of maltreatment increases vulnerability for the development of mental health problems, such as substance abuse, severe suicidal behavior, and emotional problems. In fact, as the number and type of traumatic events accumulate, the outcomes (i.e., internalizing and externalizing disorders) appear to worsen. In addition, chronicity of physical punishment during childhood also has been associated with delinquent behavior, symptoms of depression, suicidal thoughts, and alcohol abuse later in life.

Factors specific to the child, such as gender (e.g., girls are at risk of internalizing disorders; boys are at risk of externalizing) or developmental disabilities may place him or her at risk of psychiatric symptomatology. In families, greater maternal stress and poor conflict management are associated with severity of functional impairment. The combination of low family cohesion and high family conflict are common risk factors for aggression and substance abuse problems. Social and family support and placing responsibility on the adult who abused rather than the child relate to more positive mental health outcomes.

Short-Term Effects

Multiple effects have been associated with the occurrence of CPA. Behavioral and emotional difficulties include externalizing problems, such as aggression, and internalizing problems, such as anxiety or depression. Social and relationship difficulties include poor peer and adult relations that are exacerbated by difficulty managing conflict and low confidence in regulating negative mood. Cognitive and neuropsychological impairment is typically shown through skills deficits in expressive and receptive language, reading comprehension, and auditory attention. More severe forms of physical abuse result in risk of death. These include shaken baby syndrome and Munchausen's by proxy. In the latter, parents have been shown to conduct behaviors such as smothering to create a medical problem that then wins them attention.

Long-Term Effects

The potential long-term impact of CPA falls into three categories: aggression, substance abuse, and emotional problems. Aggression is expressed toward peers, family members, and dating partners and may

include violent crimes or physical abuse of one's own child. CPA is associated with substance use, more lifetime treatment, and a more severe course of substance abuse later in adulthood. For adults, a history of CPA has been found to relate to a host of emotional difficulties, including somatization, anxiety, depression, hostility, paranoid ideation, psychosis, dissociation, and self-injurious and suicidal behavior.

Treatment Approaches

Treatments for the effects of CPA are those that are directed toward child, parent, or family symptomatology and comprehensive approaches that address all persons involved or impacted. Most studies targeting child symptoms have been with preschoolers who are in a day treatment program or receiving instruction in peer relations and have shown success in increasing social skills and peer relations. One cognitive-behavioral group therapy study with school-age physically abused children found reductions on self-report measures of posttraumatic stress disorder, general anxiety, depression, and anger symptoms but no improvement on social competence and externalizing behaviors, potentially highlighting the need to include carers in treatment. In a small number of studies, parent training has been shown to decrease abusive behaviors in parents. More comprehensive models, such as cognitive-behavioral treatment with parent and child, parent-child interaction therapy, and multisystemic therapy for child abuse and neglect, are showing promise for reducing child symptoms, adult risk factors related to CPA, and re-abuse. Importantly, recent comprehensive pilot programs such as the Building Stronger Families program being implemented by the Connecticut Department of Children and Families are targeting risk factors within the family and ecology with an intensive focus on parental substance abuse.

Treatment

Definition and Epidemiology

Child sexual abuse is not a clinical disorder or diagnosis in itself. It is, rather, a variety of events or experiences to which there may be a wide range of behavioral and emotional responses. In this sense, sexual abuse is best conceptualized as a life stressor rather than as a distinct clinical entity. The legal definition of child sexual abuse varies from state to

state, and there is little consensus regarding what acts constitute sexual abuse among mental health-care providers. A common operational definition of sexual abuse is sexual exploitation involving physical contact between a child and another person. Exploitation implies an inequality of power between the child and the abuser, on the basis of age, physical size, and/or the nature of the emotional relationship. Physical contact includes anal, genital, oral, or breast contact. The definition obviously encompasses a number of different behaviors; sexual abuse is therefore not a unitary phenomenon.

It is difficult to know the exact incidence and prevalence of sexual abuse in our society because most sexual abuse is not reported immediately, and sometimes it is never reported. The Third National Incidence Study on Child Abuse and Neglect estimated that more than 300 000 children were sexually abused in the United States in 1993. However, this study includes only reported cases of sexual abuse. This is probably an underestimation of the frequency of sexual abuse, as there is evidence that only about one-fifth of true abuse cases are actually reported.

Although sexual abuse occurs across religious, racial, and socioeconomic lines, several factors may put children at higher risk for sexual abuse. There is some controversy over the relationship between social class and child sexual abuse. Some researchers have found that reported cases of sexual abuse have come predominantly from families in the lower socioeconomic levels of society, but other studies have not supported this relationship. It is likely that this apparent relationship is due to a reporting bias because economically disadvantaged families are more likely to be scrutinized by social service agencies.

Symptomatology

There is also a great deal of variability in the behavioral, emotional, and social consequences of child sexual abuse. As a group, sexually abused children have been found to manifest significantly more behavioral and emotional difficulties than do nonabused children. Some researchers have found significant levels of self-reported depression in these children, while others have not. A significant number of these children and adolescents exhibit posttraumatic stress disorder (PTSD) and other anxiety symptoms. Recent, well designed studies which have controlled for factors such as genetics and family environment variables have demonstrated that child sexual abuse significantly increases risk for adverse psychological outcomes including depression, suicide attempts, substance abuse, anxiety, and subsequent sexual assault (Brent et al., 2002; Nelson et al., 2002).

Certain clinical issues appear to be common to most sexually abused children. These include feeling different or damaged compared to other children; feeling responsible for the abuse; feeling angry, fearful, or sad; taking on inappropriate behaviors and roles (including sexual ones); and losing trust in others. Briere's research on the Trauma Symptom Checklist for Children (TSCC) provided empirical support for these difficulties. The factor analysis of the TSCC demonstrated six discrete symptom fields: difficulties with sexual concerns, dissociation, anger, posttraumatic stress, depression, and anxiety symptoms.

Finkelhor discussed four traumagenic dynamics of sexual abuse, which included traumatic sexualization, stigmatization, powerlessness, and betrayal. The Children's Attributions and Perceptions Scale (CAPS) measures issues parallel to these traumagenic dynamics, in addition to measuring attributions about the sexual abuse. This study demonstrated that feeling different from peers (stigmatization), personal attribution for negative events, impaired trust (betrayal), and decreased perceived credibility (one

aspect of powerlessness) were significant issues for sexually abused children compared to a normal control group. Wolfe et al. developed an instrument, The Children's Impact of Traumatic Events Scale (CITES) to measure abuse-specific thoughts and attributions. Factor analyses revealed distinct issues including attributions, betrayal, guilt, helplessness, intrusive thoughts, sexualization, and stigmatization. Thus, there is strong empirical evidence that sexually abused children have clinical issues and difficulties specific to sexual abuse, which can be measured by newly developed standardized instruments.

Friedrich demonstrated that sexually abused children exhibit significantly higher rates of sexually inappropriate behavior than nonabused populations. These may arise as a result of learning inappropriate behaviors through the abusive experience or from the fact that children with preexisting sexually inappropriate behavior are more likely to be targeted as victims of sexual abuse. However, there may be other, non-abuse-related reasons for children to exhibit sexually inappropriate behaviors. These behaviors are therefore not diagnostic of the sexual abuse. It is also important to note that the majority of sexually abused children do not exhibit sexually inappropriate behaviors.

It should be clear from this discussion that there is no such entity as a child sexual abuse syndrome. That is, there is no characteristic presentation that clinically distinguishes sexually abused children from non-sexually abused children. Rather, sexual abuse may result in a variety of clinical presentations. Sexual abuse therefore cannot be diagnosed by the clinical features present at evaluation. Such a determination depends on careful history taking and interviews with the child and significant others.

Assessment

Because child sexual abuse is an event (or events) rather than a clinical syndrome, and psychological responses to this experience differ considerably, one would expect psychiatric diagnoses in sexually abused children to also vary considerably. This has been documented in the literature. McLeer et al. evaluated psychiatric diagnoses in sexually abused and non-sexually abused children referred for outpatient pediatric assessment, using the Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS). The only significant difference in diagnoses between the two groups was the higher prevalence of PTSD in the sexually abused (42.3%) compared to the non-sexually abused (8.7%) children. In other diagnostic categories, there were no significant differences.

The process of determining accurate *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) psychiatric diagnoses in sexually abused children is similar to that used in nonabused populations. The issue of determining whether or not a particular child has experienced sexual abuse is a complex medical, psychiatric, and legal process, which is beyond the scope of the present article. In addition to determining DSM-IV diagnosis, there are several special areas of concern related to the sexual abuse experience that should also be addressed when assessing sexually abused children. These include possible legal involvement, child protective services interventions, medical issues related to the abuse, and other abuse-related issues of the child and family. Factors such as the type of sexual abuse experienced, how long it was going on, whether the parent(s) or other siblings also experienced sexual abuse, and the identity of the perpetrator may have direct effects on the child's and/or family's emotional reactions, attitudes, and concerns about the abuse. Some families may be most upset because the abuse involved actual intercourse, whereas to other families this may be less important than the fact that the abuse was perpetrated by a trusted family member. This information is helpful in determining appropriate therapeutic interventions.

The child's and family's perceptions of why the sexual abuse occurred are also important. Does the family blame the perpetrator, the child, the parents, or some combination? The child's symptoms may be more closely related to these attributions than to the specific details of the abuse itself. Specifically, children who blame themselves rather than the perpetrator may be more likely to feel guilt, shame, or poor self-esteem; children who blame the abuse on the unpredictability of the world may have more difficulty with fear and anxiety symptoms. Similarly, parents who blame the abuse in part on the child's behavior or appearance may be less likely to be supportive of the child, or even less likely to view the experience as abuse.

The parent's emotional reaction to their child's sexual abuse also has an effect on child symptomatology. Low levels of maternal support and maternal depression correlate with greater behavioral and emotional symptoms in sexually abused children. Higher levels of parental distress related to the child's sexual abuse have also been found to predict higher levels of behavioral problems in the child.

Because of the complex legal and child protective issues involved in cases of child sexual abuse, it is essential for the clinician to clearly define his or her role in the case. There are many differences between treatment and forensic roles, and these should be kept separate and distinct as much as possible. It

is regarded as a conflict of interest to evaluate a child for credibility of sexual abuse allegations or to evaluate a child and parents for custody determination following sexual abuse, and then to provide ongoing treatment for that child or family.

Treatment

Several randomized controlled treatment studies for sexually abused children have been published since 1990. At this time, trauma-focused cognitive-behavioral therapy (TF-CBT) has the strongest empirical support for treating this population. TF-CBT is a hybrid treatment model incorporating cognitive-behavioral principles with trauma-sensitive interventions along with family and developmental theory. TF-CBT includes the following treatment components, summarized by the acronym "PRACTICE:" Parenting skills (psychoeducation); Relaxation skills; Affective modulation skills; Cognitive coping skills; Trauma narrative and cognitive processing of the sexual abuse or other traumatic experiences; In vivo desensitization to trauma reminders; Conjoint child-parent treatment sessions; and Enhancing safety and future developmental trajectory.

Deblinger et al. evaluated the effectiveness of TF-CBT in decreasing PTSD and other psychological difficulties in 100 sexually abused children. Subjects were randomly assigned to one of four treatment conditions: child treatment only, mother treatment only, mother and child treatment, or usual community care. Children who received the TF-CBT treatment exhibited significantly fewer PTSD symptoms than children who did not receive this treatment. Children whose mothers received TF-CBT exhibited fewer externalizing symptoms and depressive symptoms compared to children whose parents did not receive TF-CBT.

Cohen and Mannarino compared TF-CBT to non-directive supportive therapy (NST) provided during individual sessions to sexually abused preschoolers and their primary caretakers. Children receiving TF-CBT showed more symptomatic improvement than those receiving NST. This differential treatment response was particularly strong with regard to children's sexually inappropriate behavior. Follow-up assessments indicated that these treatment group differences were sustained over the course of 12 months. This study also evaluated the impact of several child and family factors on treatment outcome. The strongest predictor of outcome was the parent's emotional reaction to the sexual abuse. Specifically, higher levels of parental distress at pretreatment strongly predicted higher levels of the child's post-treatment symptomatology.

In a parallel study for sexually abused children aged 8–14 years, TF-CBT was superior to NST in improving depressive symptoms and social competency. At 12 month follow-up, TF-CBT completers experienced a significantly greater improvement in PTSD and dissociation than noncompleters. Intent-to-treat analyses indicated significant group $\times$ time effects in favor of the TF-CBT group on measures of depression, anxiety, and sexual problems. In these older children, a higher level of parental support was a strong predictor of positive treatment outcome.

In a large multisite study, Cohen et al. randomly assigned 229 8- to 14-year-old sexually abused children who had experienced multiple traumas. Over 90% of this cohort met full criteria for PTSD diagnosis at pretreatment. Children were randomly “assigned” to TF-CBT or to child-centered therapy (CCT) along with their nonoffending caretaking parent. This study demonstrated that even for these multiply traumatized children, TF-CBT was superior to CCT with regard to improvement in PTSD, depression, anxiety, shame, behavior problems, and abuse-related attributions. Parents receiving TF-CBT also experienced significantly greater improvement in their own depressive symptoms and positive parenting than those receiving CCT. Thus, there is evidence that trauma-focused CBT interventions are efficacious in decreasing symptomatology in multiply traumatized sexually abused children. All of the above studies also lend support to the importance of including nonoffending parents in treatment. More research is needed to further assess the efficacy of CBT and other potentially effective interventions and to clarify what components of these treatments may be most effective for which subgroups of children. Such TF-CBT treatment interventions may be provided either individually or in a group setting.

Other CBT-related approaches have been developed and are currently being tested for adolescents experiencing chronic PTSD related to sexual abuse. For example, the SPARCS (Structured Psychotherapy for Adolescents Recovering from Chronic Stress) and STAIR (Skills Training in Affective and Interpersonal Regulation) models show promise in this regard.

Other approaches to treating sexually abused children have received less empirical evaluation. One study has evaluated the efficacy of psychodynamic therapy for this population. Trowell and colleagues randomly assigned sexually abused children to 18 sessions of psychoeducation groups or 30 sessions of individual psychoanalytic therapy. The psychoanalytic group experienced greater improvement in PTSD symptoms, but the design of this study makes it difficult to determine whether this differential response was due to treatment type (psychoanalytic vs.

psychoeducation), modality (individual vs. group), or dosage (30 sessions vs. 18). There are probably many efficacious therapeutic techniques for sexually abused children. Follow-up studies have indicated that many sexually abused children recover fully from this stressful experience and do not suffer ongoing negative sequelae. Hopefully, future research will more clearly elucidate which treatment approaches are most likely to result in this positive outcome.

Introduction

Physical Outcome

Maternal Satisfaction

Psychopathology

Conclusion

Glossary

<i>Baby blues</i>	A short period of mood swings and emotional reactivity in the 2 weeks following childbirth.
<i>Epidural anesthesia</i>	Analgesia injected into the space around the spinal cord to block pain in the abdomen.
<i>Episiotomy</i>	A cut made to the woman's perineum to help the baby be delivered.
<i>Intrapartum Oxytocin</i>	During labor. A hormone used to induce labor and stimulate contractions of the uterus.
<i>Parity</i>	Number of live children born to a woman.
<i>Polymorphic (cycloid) psychosis</i>	Psychosis with rapidly changing and variable psychotic symptoms and emotional states as a cardinal feature.
<i>Postnatal depression</i>	Depressive disorder in women in the year following childbirth.
<i>Postpartum</i>	After childbirth.
<i>Prophylaxis</i>	Measures taken to prevent a disease.
<i>Puerperal</i>	Pertaining to childbirth.

Introduction

Childbirth is an intense event that involves extreme physical stress and carries emotional, cognitive,

social, and cultural significance. Physically, women have to cope with acute changes as the uterus contracts, the cervix dilates, and the baby and placenta are delivered. General responses to stress such as release of endorphins, epinephrine, and catecholamines have been shown in laboring women, as well as increases in cardiac output and blood pressure. Emotionally, labor and the birth of the baby usually involve intense positive and negative emotions. Cognitive demands are also placed on the woman as she copes with the events of birth. Interpersonal dynamics between the woman and her birth partner and medical attendants can be supportive or can increase stress levels if birth attendants are perceived as unhelpful or dismissive. Finally, birth and motherhood are associated with many cultural expectations and perceived norms. In Western societies, for example, birth is highly medicalized, yet often emphasis is placed on women trying to achieve a so-called natural birth with minimal intervention or pain relief.

Childbirth is therefore an intense acute stressor that many women go through. It also enables the study of the interaction between pre-event and event factors in perceived stress and the effect of this on physical and psychological outcomes. This is consistent with the diathesis stress approach to health outcome, in which pre-existing vulnerability (physical, psychological, and social) interacts with event characteristics to determine outcomes. However, the classification of childbirth as an acute stressor is rather artificial, and the impact of childbirth must be placed in the context of previous adjustment to pregnancy and postnatal adjustment to motherhood and a new baby, both of which are also potentially stressful and difficult.

Research into the role of psychosocial factors in birth outcome has generally established that

psychosocial factors are important in physical outcomes, such as morbidity and mortality, and psychological outcomes, such as maternal satisfaction and psychopathology. The postnatal period is associated with a number of psychological problems that are seen as specific to childbirth, namely, the baby blues, postnatal depression, and puerperal psychosis. However, it is still debated whether childbirth has specific effects that distinguish postnatal psychopathology from psychopathology occurring at other times. More recently, childbirth has also been linked with posttraumatic stress disorder.

The experience of birth and the outcome of birth are therefore influenced by multiple psychosocial factors. The importance of these factors varies for different outcomes and between individuals. For example, a woman with a history of psychological problems may have a high vulnerability to postnatal psychopathology, so other factors during and after birth may not be as important as they are for a woman with no previous history of psychological problems. This is one of the challenges of research in this area, and it is therefore an area characterized by conflicting findings. It is thus important to consider methodological quality of studies and weight of evidence when drawing conclusions. This article provides a brief overview of some of the current research and understanding of psychosocial factors that are important in three broad areas of birth outcome: physical outcome, maternal satisfaction, and psychopathology; then it looks generally at what conclusions can be drawn regarding childbirth and stress.

Physical Outcome

The physical outcome of birth includes complications during birth, type of labor and delivery, and complications with the infant. As in other areas of health, low socioeconomic status is associated with increased complications of birth (e.g., pre-term labor) and maternal and infant morbidity (e.g., low birth weight) and mortality. It is hypothesized that the effect of low socioeconomic status is due to material deprivation but is mediated by psychosocial factors such as level of education, access to information, a lack of social support, and negative life events. These in turn may lead to stress, anxiety, lowered self-esteem, and depression, with cognitive problems such as dysfunctional attitudes, which result in a set of maladaptive coping strategies such as learned helplessness and risk taking.

It is well established that the physical outcome of birth can be affected by psychosocial factors during pregnancy and birth such as support or anxiety. In the literature, continuous support during labor has

received the most attention. A series of experimental studies has been carried out in countries where it is usual for women to give birth without a birth companion. These studies compare women allocated a doula during birth to women who have no birth companion. A doula is a layperson (usually female) trained in supporting laboring women, but not medically qualified. A review of 15 doula studies involving over 12 000 women showed that women with the continuous support of a birth companion used less analgesia during birth, were less likely to have an operative birth, and were less likely to report dissatisfaction with their birth experiences. In general, continuous support during birth was associated with greater benefits when the provider was not a member of the hospital staff, when the support began early in labor, and in settings in which epidural analgesia was not routinely available.

A number of explanations have been put forward for why support in labor has such a powerful effect on birth outcome, and these typically focus on biological or psychological mechanisms. From a biological perspective it has been hypothesized that the complicated neuroendocrinal control of labor and birth can be disrupted by stress in various ways, reducing the efficacy of the birthing process. For example, it has been posited that labor pain leads to a strong stress response, resulting in increased autonomic activity, uncoordinated uterine contractions, and abnormal fetal heart rate, which all impede the progress of labor. Whether this effect is a direct result of the pain or is mediated by stress or anxiety is not established.

Psychological explanations suggest that support in labor improves outcomes by increasing women's feelings of control and competence, decreasing the stress response, and thereby reducing the necessity for medical interventions. Emotional support may also reduce fear and anxiety and their associated effects.

Maternal Satisfaction

Research looking at maternal satisfaction has largely focused on women's satisfaction with the birth generally and has not looked at specific elements such as satisfaction with coping, birth outcome, and health-care provision. The main factors during birth that have been examined in relation to maternal satisfaction are support during birth, pain relief, perceived control, and levels of intervention during birth. For example, as previously discussed, continuous support during labor is associated with increased maternal satisfaction, as is continuity of care. It was found that women assigned to a one-to-one midwifery care model, who were cared for by the same caregivers throughout their pregnancy and birth, reported

significantly more satisfaction with their experience than women assigned to obstetrician-led care who met different caregivers at each visit, without any difference in clinical outcome.

Most research on satisfaction with the birth experience has focused on pain relief, in the belief that if the pain is controlled or alleviated the experience of giving birth will be more positive. This appears to be the case, with studies showing that women who receive more effective pain relief rate their experience as more satisfying. However, most studies have shown that satisfaction is high overall, regardless of pain relief received, suggesting that many other factors are also important. A woman's expectation of the pain may play a role, with research showing that women who expect more pain are likely to be more satisfied afterward. Furthermore, if women expect to be able to give birth without pain relief, they report a decline in satisfaction if they did have to use analgesia, notably epidural anesthesia.

Other factors associated with maternal satisfaction are personal control, having expectations met, and social class. Extensive medical interventions (electronic fetal monitors, episiotomies, perineal shaves, and enemas) are negatively correlated with maternal satisfaction. However, active management of labor (e.g., early rupturing of membranes, vaginal assessments, and early use of oxytocin for slow progress) does not affect women's satisfaction overall compared to routine management.

A systematic review concluded that expectations, support, the quality of the caregiver-patient relationship, and involvement in decision making (control) are the most important factors in determining maternal satisfaction. Secondary factors are pain, socioeconomic status, preparation for birth, interventions, and continuity of care.

Psychopathology

Baby Blues

The baby blues are a period of emotional lability and overreactivity that appears in the first 2 weeks following birth. The blues do not seem to be part of a continuum with postpartum depression or puerperal psychosis, and sadness and depression are not typical features. Instead, women seem to exhibit mood fluctuations such as elation, hostility, tearfulness, and general lability of affect. Some women who experience severe blues will go on to develop postnatal depression. The blues affect between 26 and 85% of women, the variability in figures being due to the fact that the baby blues are not classified as a psychiatric disorder and therefore not uniformly defined.

Several competing theories have been proposed to account for the blues, most notably a hormonal/biological account, suggesting that the large fluctuations in hormones following delivery are responsible. The changes in concentrations of hormones such as estrogen, progesterone, and cortisol are hypothesized to cause a neurotransmitter imbalance, which is expressed by widely fluctuating moods. It has been suggested that this could be evolutionarily adaptive, as this excessive emotionality separates the mother from her usual concerns and makes her available solely for the baby, facilitating mother-baby bonding. Historically, it may also have been responsible for promoting some of the rituals that surround the birth of a baby, such as extensive periods of confinement and good support for the mother. However, there is no consistent evidence linking changes in hormone levels with fluctuating postnatal mood. Other theories suggest that psychosocial factors are important. While demographic factors such as age and race are not predictive of the baby blues, in the West the blues have been associated with economic insecurity and lack of social support. It has also been proposed that it may be a grief reaction in women who have been disappointed with pregnancy and birth events and outcome, and has been shown to be correlated to pessimism in late pregnancy.

The baby blues appear to be time limited and require no specific treatment other than support. However, the blues should be distinguished from depression and sadness in the immediate postpartum period, which is predictive of postnatal depression later.

Postnatal Depression

Postnatal depression (PND) is the most well known of postpartum psychiatric disorders. Between 10 and 20% of women are believed to suffer from it during the first year after birth. However, the disease still remains underdiagnosed and undertreated. Recently, controlled studies have shown there is no significant difference between postnatal women and appropriate female controls in the incidence of depression. Therefore, postnatal women are no more at risk of developing depression than at other times in their lives. However, it is argued that PND has a greater psychosocial impact than depression at other times in a woman's life, as it can cause considerable strain in relationships and family life, affect the mother-infant relationship, and possibly also affect the infant's development. Currently self-report scales are used to screen for depression in postnatal women. These screening tools can be a useful measure for identifying women at risk, although patients who score above

threshold on screening questionnaires are heterogeneous and may be suffering from anxiety, obsessive, or posttraumatic stress disorders.

Like the baby blues, postnatal depression has also been postulated to be a result of a hormone imbalance in the period following birth. A large drop in levels of estrogen and progesterone occurs after birth, suggesting that postpartum mood changes can be explained by the effect of the withdrawal of these hormones. This has been supported by studies in which women were administered these hormones in the postpartum period, resulting in alleviation of the depression. A further hypothesis is that hormonal changes trigger pathological mechanisms at the neurotransmitter level, resulting in depression. However, many studies measuring levels of hormones in women after birth have found no differences in hormone concentrations between women with and without depression, suggesting that the link between hormone levels and depression is weak if not nonexistent.

It has been argued that because prevalence of PND is no greater than depression in women in general, PND should be seen as primarily a psychosocial disorder. Studies have shown associations with previous depression and other psychiatric illness, stressful life events, and disturbed relationships. Other predictors include high parity, stress in pregnancy, social isolation, material deprivation, and low social support. A history of depression, and depression during pregnancy, appear to be some of the strongest predictors of PND. Furthermore, genetic factors have been shown to explain 25–38% of the variance. The psychosocial model would suggest that good social support following childbirth would protect women from depression, and studies seem to bear this out. If, as suggested, prevalence of depression postnatally is not greater than prevalence in women of childbearing age in general, and if PND is related to similar factors to depression in nonpostnatal women, it may be hypothesized that PND is not a separate illness from depression in general.

Puerperal Psychosis

Puerperal psychosis (PP) is a rare disorder occurring in about one woman in a thousand following childbirth. It generally takes the form of mania, severe depression (with delusions, confusion, or stupor), or acute polymorphic (cycloid) psychosis. It does not overlap completely with bipolar mood disorder, although there is evidence of a link between the two, especially as the majority of patients presenting with a severe postpartum psychiatric disorder appear to have a cycloid psychosis. It has been proposed that PP may be one of a spectrum of bipolar disorders. In susceptible women, childbirth, abortion, and even

menstruation can trigger bipolar episodes. However, other researchers propose that PP has a pattern of symptoms unlike any other psychiatric disorder; for example, patients exhibit a high rate of disorientation, confusion, and depersonalization. Hallucinations appear in about half of patients with PP, suggesting an overlap with schizophrenia, and mania is not as pronounced in postpartum patients as in those with a diagnosis of bipolar disorder. Thus, some argue that PP is a separate disorder from other psychoses.

Puerperal psychosis appears to be highly heritable, with 10–25% of relatives of women with PP having some kind of severe psychiatric disorder. It also tends to recur, with a chance of about 1 in 4 in each pregnancy. It can be treated safely with newer neuroleptic drugs. In certain circumstances electroconvulsive therapy can be useful, and lithium has been explored as a prophylaxis.

Postnatal Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is characterized by three types of symptoms: re-experiencing (flashbacks, nightmares), avoidance (of reminders of the stressor, emotional numbing), and hyperarousal (insomnia, difficulties concentrating). There is converging evidence that approximately one-third of women appraise their birth experience as traumatic and 1–2% of women will develop PTSD after childbirth. Case studies suggest that the disorder might result in an impaired mother–baby relationship, sexual dysfunction, and fear of subsequent childbirth (tokophobia), although this has not yet been confirmed by quantitative research.

Studies of factors associated with postnatal PTSD suggest an interaction between prenatal factors, birth experience, and postnatal factors. The type of delivery appears to be important, with women who undergo operative deliveries more at risk of postnatal PTSD. However, this is not a consistent finding. Indeed, one study noted that the majority of women with PTSD had an obstetrically normal vaginal delivery. Thus, in common with PTSD following other events, there is unlikely to be a direct relationship between the severity of birth and PTSD. Other labor and birth characteristics variously associated with rating birth as traumatic are medical intervention, pain in first stage, a long labor, feelings of powerlessness, and receiving inadequate information. PTSD has been associated with feelings of fear for self and baby during labor and birth. It has also been found that low control, higher trait anxiety, and greater fear were associated with symptoms of PTSD.

Several prenatal vulnerability factors have been investigated, and those that emerge as important are a history of trauma or psychological problems and

possibly trait anxiety. Dysfunctional attitudes are predictive of postpartum depressive symptoms, and it has been hypothesized that there are cognitive vulnerabilities to PTSD as well, although this has not yet been examined in relation to postnatal PTSD. Postnatally, social and professional support in the period after birth may be a protective factor, and aftercare trauma services might be useful. Several studies have analyzed the effectiveness of debriefing services with a midwife or doctor following birth in preventing PTSD, but results have been inconsistent.

Conclusion

The association between different psychosocial factors and the outcomes discussed in this article demonstrates the complexity of this field. In summary, physical outcomes are associated with socioeconomic status and continuous support in labor. Maternal satisfaction is associated with expectations, support in labor, the quality of caregiving in labor, and involvement in decision making. Postnatal depression is associated with previous history of depression or other psychiatric illness, additional stressors, and low social support. Puerperal psychosis is associated with a personal history or family history of psychiatric illness. Postnatal PTSD is associated with a history of trauma and psychiatric illness, type of delivery, and life threat.

Models of the interaction between prenatal, birth, and postnatal factors therefore tend to be complex psychosocial models. However, it could be argued that models specific to childbirth are not necessary, as, in many cases, the determinants of postnatal psychopathology are similar to psychopathology at other times. For example, the finding that postnatal depression is associated with previous depression, additional stressors, and low social support is similar to research findings regarding vulnerability to depression generally. Equally, the finding that there is no dose-response relationship between the obstetric severity of birth and postnatal PTSD is comparable to research into PTSD following other events. This etiological similarity between postnatal psychopathology and psychopathology at other times implies that stress and coping processes similar to those in other types of life events act to determine the outcome of childbirth. Therefore, childbirth can be used as a research paradigm with which to study stress processes and outcomes that generalize to other acute life events. As such, it may also help us better understand the complexity of stress processes.

Definitions of Stress

Measurement of Stress

Effects of Stress

Glossary

<i>Contextual threat</i>	The level of threat caused or implied by the life event to an average child of the same age, sex, and biographical characteristics as the child in question.
<i>Life event</i>	Any event or circumstance occurring in the life of a child that may have the potential to alter his or her present state of mental or physical health.
<i>Limbic kindling</i>	A psychophysiological process in which the limbic system (a border between the new and the old brain, forming a circuit primarily concerned with emotions, memory, olfaction, and neuroendocrine control) receives electrical stimulation resulting in increased responsiveness to low levels of stimulation over time. In this way, repeated traumatization, as in child abuse, or a trauma followed by intrusive memories could kindle limbic nuclei, leading to behavioral changes.
<i>Long-term psychosocial experience</i>	Ongoing process in which the delineation of a beginning and end stage is not always possible. The experience may be adverse (e.g., parents' marital disharmony or financial hardship), desirable or hedonically positive (e.g., a rewarding hobby), or socially required for normal development or for protection against negative experiences (e.g., supportive relationship with a parent or having a close friend).
<i>Modifier</i>	A variable, aspect, or characteristic that exerts modifier effects on risk. If the risk is intensified, then the variable carries a vulnerability effect; if the risk is diminished, then the variable carries a protective effect. A vulnerability/protective factor is a moderator and is demonstrated statistically with a significant interaction effect.

Negative life event

A life event exerting a particular undesirable impact on the child.

Positive life event

A life event that is hedonically positive, enhances self-esteem, or has a beneficial effect on the child's life circumstances.

Risk factor

A variable that negatively influences outcome regardless of the presence or absence of adversity.

Stress, stressor, and stress reaction

A form of stimulus, an inferred inner state, and an observable response reaction, respectively.

Definitions of Stress

Stress, Stressor, and Stress Reaction

Child stress can be defined as any intrusion (stressor) into children's normal physical or psychosocial life experiences that acutely or chronically unbalances physiological or psychological equilibrium, threatens security or safety, or distorts physical or psychological growth and development and the psychophysiological consequences (stress reaction) of such an intrusion or distortion.

Harmful vs. Beneficial Stress

The traditional view of stress as a significant discrepancy between the demands of a situation and the organism's capacity to respond, resulting in detrimental consequences, implies that all stress is harmful. However, as far as children are concerned, the opposite is sometimes true. Mild stressors are often benign and sometimes even growth promoting.

Additive and Synergistic Stress

Apart from their individual effects, stressors can also act additively and synergistically. For example, deprivation and malnutrition can each compound fetal alcohol effects. Even the same cause can stress the child through two or more different mechanisms. Thus, maternal alcoholism can stress the fetal brain chemically and then psychologically stress the newborn infant through maternal unavailability, neglect, or abuse. Poverty can stress the child through malnutrition, inadequate environmental stimulation, and poor parenting due to worry, preoccupation, and discouragement.

Measurement of Stress

Chronic Stress

There exist a variety of questionnaire and interview instruments for the assessment of chronic stress in

children, usually stemming from enduring adverse circumstances such as environmental or socioeconomic deprivation, parental unemployment or illness, and family discord or criminality. Also, the two widely used diagnostic classification systems, the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) and the *International Classification of Diseases* (ICD-10), contain a separate axis for systematic measurement of stressors of likely relevance for children's health.

Life Events

Questionnaire measures The first-generation measures of stress in childhood were based on the questionnaire format to provide overall scores of degree of life change. The assumption was that change per se, not necessarily the unpleasant nature of the experience, was stressful for children. In parallel with these overall approaches, numerous studies of specific life events such as family breakup, bereavement, and disasters such as floods, earthquakes, or hijacking were carried out.

Interview measures

The meaning of life experiences The realization that it was necessary to take into account the social context of life events in order to assess their meaning and hence their stressful quality constituted perhaps the most significant conceptual advance. The clear implication of this advance was that interviews rather than questionnaire approaches were needed for adequate assessment of life events.

Undesirability, cognitive appraisal, and independence A major reappraisal of psychosocial stress research involved the emphasis on the need to differentiate between desirable and undesirable life changes and to highlight the role of cognitive appraisal of the events. The distinction between life events that could have been brought about by the person's own actions and those that are independent of behavior constitutes another conceptual advance. This distinction is especially important when considering stressful life events as causal agents for psychiatric disorders.

Contextual threat The concept of contextual threat has represented a decisive step in the assessment of children's life events. In determining the stressful quality of life events, it is necessary to take into account their social context, i.e., their meaning to an individual. For example, it is unreasonable to treat moving as a unitary event. The effects would be very different for a child who moved within the same neighborhood and maintained the same school and

friends compared to one whose new home was in another town, or even another country, resulting in loss of friends, surroundings, and school. To understand this difference, interviews rather than questionnaire approaches are needed.

The assessment is usually made separately for short-term (based on immediate impact), and long-term (the likely impact occurring some 10 days later) threat. In addition, it has become customary to conceptualize the overall rating of contextual threat as being made up of one or more components that vary somewhat depending on the instrument used. These components commonly include the following: loss of an attachment figure (e.g., losing a parent or a close friend), loss of a valued idea (a major disappointment, letdown, or humiliation), risk of loss of attachment figure (the threat of losing someone close), physical jeopardy (being in physical danger due to accident, etc.), trauma as witness (being witness to an unpleasant or frightening incident), and psychological challenge (the event involving the subject in a new role or with new responsibilities).

Some life events encountered by children rate high on contextual threat because they cause a major alteration in the life circumstances (e.g., the death of a parent). In other events, the threat is primarily cognitive. This means that the event may not result in any actual change in the external environment, but instead drastically changes the child's perception of an aspect of him- or herself, or of other people or things in a way that presents a threat to the child's self-esteem (e.g., severe humiliation) or reduces his or her perceived sense of security (e.g., a parent threatening to abandon the child). Life events may also involve a combination of real life change and cognitively mediated threat (e.g., the parents' marital separation).

Effects of Stress

Developmental Interferences

Physical development The ill effects of compromised prenatal, perinatal, and early postnatal care on the child's development and well-being have long been recognized. For example, in the multiple associations between prematurity, illness, and outcome, environmental factors are known to play a central role. Likewise, children suffering from the nonorganic failure to thrive syndrome frequently exhibit a complex entanglement of caloric and protein intake, touch, and the release of growth hormone.

Neurodevelopment

Neuroanatomy Stress can also influence the development of the brain. To develop properly,

undifferentiated neuronal systems are dependent on environmental cues such as neurochemical and hormonal factors. These processes in turn are dependent on the child's sensory experiences. A narrow window appears to exist during which specific experiences are required for the optimal development of the brain. After birth, brain development mainly consists of an ongoing process of wiring and rewiring. Early experiences can, for example, cause the final number of synapses to increase or decrease. Infants confined to their cots and with little opportunity to explore or experiment, and who are rarely spoken to, may fail to develop neural pathways that facilitate later learning.

Neurotransmitters and hormones play a major role in neuronal migration, differentiation, and synaptic proliferation. Massive increases in catecholamine activity caused by severe or prolonged stressors are expected to have a significant impact on brain development. The hippocampus is a likely target for the effects of early stress because neurogenesis in this area continues into postnatal life. The amygdaloid nuclei are critically involved in the formation of emotional memory and in stress-induced memory enhancement. Repeated trauma may lead to limbic kindling. Thus, during critical periods in early childhood, experiences can organize brain systems; nurture may become nature. This would also suggest that it is more appropriate to speak of early childhood malleability than resilience.

Primate research has presented strong evidence that chronic unpredictable stress during pregnancy may have long-lasting effects on brain activity and behavior of the offspring. Furthermore, prenatal stress appears to be capable of affecting the neurobiology of the neonate so that its responses to common events and stimuli are markedly altered. These effects on brain mechanisms are more likely to be diffuse, rather than specific. As a consequence, the neonate may, for example, be more fussy and difficult, affecting how the caregiver is able to cope. Thus, prenatal stress appears to set the infant's neurobiology into a state in which vital attachments are hard to achieve and adverse experiences are more likely. The adverse experiences can in turn result in further neurobiological deflection of development.

Prenatal effects on fetal neurobiological development may also be easily confused with genetic predisposition. It therefore remains a challenge to determine how prenatal environment contributes to persisting and traitlike organization of neurobiological systems. This, in turn, would markedly further our understanding of how genetic and postnatal environmental factors play a role in the expression of developmental psychopathology, for example.

Neurophysiology When a child is exposed to a strong stressor, a series of interactive, complicated neurophysiological reactions take place in the brain, the autonomic system, the hypothalamus-pituitary-adrenocortical axis, and the immunosystem, with concomitant release of stress hormones. Neurophysiological activation during acute stress is usually rapid and reversible. As such, it has an adaptive purpose. Following severe prolonged or repeated stress, however, these changes may no longer be reversible, and become maladaptive. One explanation for this is that the organisms have not yet evolved mechanisms to deal adaptively with chronic stress. Stress-induced sensitization may also occur, with the systems underlying the stress response becoming more sensitive to future adverse experiences. Children growing up in a persistently threatening environment develop stress response systems in midbrain and brain stem that are overreactive and hypersensitive. This development may be highly adaptive, but only as long as the child remains in a violent, chaotic environment. Profound cognitive disturbances can accompany this process.

Some young children, especially girls, however, react in the opposite way by freezing rather than by becoming visibly anxious or hyperactive. Flooding of adrenocortical hormones during periods of acute stress may also have negative consequences on memory and the anatomical substrates of memory.

Trauma response Traumatic events impact structures in the central nervous system – though the exact mechanism of this remains unknown at present. Structures underlying cognitive, affective, sensory, integrative, regulatory, neuroendocrine, and motor functions are coordinated in the life threat response. This may lead neuronal networks, excited during a life-threatening event, to become identified for later potentiation, forming the basis for permanent registration in memory.

In younger children whose brains are maturing in use-dependent interaction with their environment, aspects of such memory states may become lifelong traits. It has been suggested, for example, that children using a dissociative adaptive defense in an acute response to trauma would later demonstrate primarily dissociative or somatic symptoms. On the other hand, children who primarily use hyperarousal adaptation to an acute stressor would be more likely to develop chronic hyperarousal symptoms, such as startle response, anxiety, motor hyperactivity, sleep disturbance, or tachycardia.

Psychological development

Cognitive development Persistent environmental stress and deprivation can significantly impair the

development of the child's cognitive abilities, including attention skills, memory, and language as well as intellectual capabilities. Conversely, a child's level of cognitive development is an important determinant of how he or she will deal with trauma. Ability to label and express feelings, to receive reality-based feedback, and to incorporate the experience into a narrative are relevant developmental achievements.

Emotional development Because a child's most pressing emotional needs change over time, a particular trauma may have more influence during one stage of development than during another. The cognitive interpretation of the same trauma may also be different depending on the child's developmental level.

Effects on Physical Health

Numerous studies in the fields of pediatrics and psychosomatic medicine have shown that children with increased psychosocial stress are significantly more likely to experience illness and hospitalization as well as use health services more frequently than other children. Stress as a precipitating and/or provoking factor has been implicated for asthma, appendicitis, rheumatoid arthritis, and leukemia, for example. High levels of psychosocial stress have also been shown to predict greater morbidity in children who already have a chronic disease. For example, recent studies on children with asthma have demonstrated time-related associations between exposure to stress and acute worsening of symptoms.

The role of stress in viral infections has been the focus of research in more recent years. Well-controlled prospective and experimental studies have shown that adverse life events and other stressful experiences significantly increase a person's susceptibility to acute and recurrent respiratory infections. One likely explanation for this association is that stress compromises the body's immune responses, with individual differences in susceptibility possibly being accounted for by differences in psychobiological reactivity. It is acknowledged, for example, that the immune system and the central nervous system form a bidirectional communication network. In this network, pro-inflammatory cytokines play a critical role.

Effects on Mental Health

A range of research strategies have demonstrated beyond all reasonable doubt that psychosocial factors exercise causal effects on children's psychosocial functioning. They also have contributed in a major way to the multifactorial causation of psychiatric disorders in childhood. In this respect, the main risk

stems from chronic psychosocial adversity such as unhappy family life, parental psychopathology (including substance abuse and criminality), and parental stress caused by poverty or unemployment, or being a victim of bullying or other victimization. Acutely stressful life events, especially those that carry long-term threat to the psychological security of the child, add to the risk caused by chronic stressors, and in some instances constitute sufficient risk in their own right. Negative life events that are associated with chronic psychosocial adversity, rather than those that arise out of the blue, have also been shown to provoke an onset of psychiatric disorder, particularly depression, in children. Their main effect, however, appears to be to determine the timing of a new episode of disorder in a child already at risk due to chronic stress or made vulnerable through lack of emotional support.

Reasons for Individual Differences

Personal vulnerability Compared with adults, far less work has been carried out to examine the importance of personal vulnerability to stressful experiences in children. The role of close, supportive relationships, however, has received support. Thus, difficulties in the child's own friendships as well as their mother's lack of confiding relationships have been shown to predict depression and other emotional disorders. Likewise, the overall risk of psychiatric disorder in the presence of severely negative life events is significantly enhanced in children lacking a confiding relationship with a parent or a close adult relative.

Exposure to stressful experiences The very large individual differences in children experiencing stress and adversity are acknowledged. A variety of explanations are likely to apply. First, some stressful life events represent chance or acts of fate, including natural and man-made disasters such as war, floods, earthquakes, and shipping accidents. Second, stressful life events can also be a function of structural factors in the society, making negative experiences much more likely in some segments of the population than in others. In children, the effect of low social class on stressful life events appears to be an indirect one, via chronic psychosocial adversities such as family ill health and interparental conflicts, which in turn increase the likelihood of acute negative events. Likewise, family poverty is associated with multiple risk factors for children. Many of these risks are mediated via parental responses to such pressures. Being poor is linked with chronic psychological distress in parents, thus impeding effective parenting through harsh discipline, inconsistency, lack of monitoring, family

conflict, and multiple changes in family configuration. Third, many of the stressful life events occurring to children are a function of their parents' behavior in one way or another. This is the case with divorce, abuse, and a parent being arrested, for example. Such stressful, family-dependent life events tend to be rooted in parental psychopathology, substance abuse, or criminality.

Genetic factors are also implicated as bases of individual differences in environmental risk exposure – a phenomenon known as gene–environment correlation. The parents who pass their genes to their children are usually the same parents who provide the rearing experience. For example, antisocial adults are much more likely than other people to provide negative rearing environments to their children. Antisocial behavior in one or both parents in turn predicts a much increased rate of marital breakdown and negative parent–child interactions and, hence, life events that are stressful to children. Gene–environment correlation can also lead to environmental risk that impinges differently on the children.

Susceptibility There are large individual differences in children's responses to stressful life experiences. A major reason for this may lie in the crucial importance of the personal meaning of the particular experience involved. In addition, previous experiences are likely to color a person's reaction to a new experience. Stressful life events can be strengthening as well as weakening; they can steel as well as sensitize. Other factors determining individual differences are the child's age, sex, temperament, locus of control, and family support.

Several other explanations may account for the individual differences. One of these is gene–environment interaction, a concept introduced more recently. In this case, the vulnerability to stress is viewed as being genetically determined rather than acquired through experience.

Mechanisms

Additivity of stressful experiences There is no doubt that a single major life event such bereavement or kidnapping can be quite sufficient on its own to provoke psychiatric disorder. However, it also appears that there is a cumulative effect when several major life events occur together during a short period of time. Likewise, the multiplicative effect of the co-occurrence of several chronic adversities has been demonstrated in children.

Potentiation of stress Chronic adverse circumstances such as unhappy family life; parental psychopathology, substance abuse, or criminality; economic

hardship; or stressors in the school environment all in themselves increase the risk of child psychiatric disorder. Their presence also makes it more likely that acute stressful events will occur, often stemming directly from the ongoing adversity. Discord leading to divorce or criminality resulting in jail sentence, from the child's point of view, both involve separation from a parent. Apart from increasing the likelihood of stressful life events to occur, chronic adversity is also apt to potentiate their adverse effects.

Vulnerability and protective mechanisms There also exist complex vulnerability and protective mechanisms, i.e., those that increase and those that decrease stress effects. These include interactions, not just main effects. Such mechanisms need to be considered in relation to the child's individual characteristics as well as to their experiential properties.

A moderator is a variable that influences the strength or the direction of a relationship between a predictor variable and a criterion variable. An example is a finding that in the context of a child's chronic physical illness, family stress is negatively associated with child psychological adjustment. When the nature of the association is further examined, it may turn out that the effect is stronger (or weaker) in the presence of other contextual variables. For example, the strength or the direction of the relationship between stress and adjustment may depend on the type of coping used by the family. That is, a significant association may emerge only when a parent (or child) copes in a maladaptive manner.

A protective factor either ameliorates negative outcomes or promotes adaptive functioning. The protective factor serves its protective role only in the context of adversity; a protective factor does not operate in conditions of low adversity. Conversely, a vulnerability factor is a moderator that increases the chances for negative (maladaptive) outcomes in the presence of adversity. Similar to a protective factor, a vulnerability factor operates only in the context of adversity.

Mediating mechanisms There are a number of mechanisms through which psychosocial stressors lead to child disorder. Some acute life events bring about lasting adverse alterations in life circumstances. Examples include bereavement and parental divorce. Thus, for a child, the ill effects arising from the loss of a parent are highly dependent on whether the loss is associated with family discord or leads to serious impairment in parenting. Loss that does not have these adverse sequelae may be painful at the time, but usually remains of limited significance as a causal factor for persisting disorder.

Stress may also be associated with loss that is only in the person's mind. The mechanism of cognitive threat is a likely possibility. Young children, for example, appraise their situation and contemplate their life circumstances in ways that differ from those typical of adults.

Recurrent hospital admission is a known stressor in young children, with the key mediating mechanism being the disturbed parent-child relationship engendered by the child's behavior upon the return home. A comparable situation is the birth of a sibling. Here the disturbance of the prior parent-child relationship is more important, suggesting that the main stress for the child may reside in the parental reaction rather than in the child's response to the event as such.

Chain events With children, it is also important to consider mediating mechanisms in long-term consequences, i.e., how adverse early experiences influence later psychosocial functioning. The sequelae frequently depend on chain events that involve a number of different links reflecting separate psychological processes. These include learned maladaptive emotional responses, self-perpetuating behavior patterns or habits, lowered self-esteem influencing the ability to deal with future experiences, poor coping skills, internal working models of insecure relationships, or behavior that serves to shape later environments or increase the individual's exposure to stressful life events.

Positive experiences as protectors Compared with the volume of research that has been carried out on the effects of negative experiences on children's health, studies examining the role of positive life experiences are lacking. Furthermore, the meager evidence available so far fails to support the notion that hedonically positive events and life situations would have an ameliorating effect on psychiatric risk. The situation, however, may be different with regard to somatic manifestations of illness. Positive life events have been shown to offset the increased risk for new asthma exacerbations associated with severely negative life events.

Beneficial stress There are both beneficial and harmful stress experiences. The distinction is likely to lie in the child's temperamental qualities and in how the particular past experience has been coped with. This has implications for prevention. It is possible that successful prevention only partly lies in the avoidance of stressors, but largely lies in helping children to overcome negative experiences. The overcoming of stress can be strengthening, ensuring that

children encounter stressors at times and in ways that make it more likely that they will come out on top with a sense of accomplishment rather than with feelings of fear and humiliation.

Turning points Turning points in development is another issue likely to affect long-term sequelae of childhood stress. A turning point refers to an experience either internal (as with puberty) or external (as with dropping out of school) that carries with it the potential for enduring change because the experience either closes doors or opens up opportunities, or because it is associated with a lasting alteration in life circumstances. Most turning points concern very ordinary life experiences, but, in each case, the particular individual circumstances are crucial. Therefore, life events need to be conceived of not just in terms of their threat features, but also in terms of their effects on the person's social group and life opportunities.

Specificity of stressors vs. specificity of outcome It is conceivable that specific associations between particular stressors and particular outcomes are mediated by psychological, biological, or social processes and the specific nature of the stressor. Little evidence of this, however, exists so far. This may be because until recently very few studies testing full specificity designs (i.e., specific stressors linked to specific outcomes, via specific mediators, in the context of specific moderators) have been carried out in children. Across the various stressors such as exposure to poverty, illness, marital conflict, divorce, violence, or abuse, the only consistent evidence appears to be in relation to sexual abuse. Sexual abuse has been found to be associated specifically with internalizing problems, posttraumatic stress disorder, and sexual acting out.

The lack of specificity may have several explanations, including significant rates of co-occurrence and comorbidity of psychopathology in childhood, the lack of a well-established taxonomy of stressors, and the fact that specific characteristics and environmental contexts of the child moderate the associations between stressor and outcome in unique ways. Particular stressors may also be linked with particular outcomes only in the presence of particular moderating and mediating processes. Furthermore, stressors categorized by type may include a variety of stressors that are different in nature. It is known, for example, that poverty is associated with a range of additional stressful experiences, which include conflict (e.g., exposure to violence, physical abuse, divorce/marital conflict) and stressors involving loss (e.g., deaths, separations, disasters).

Structure and Function of Cholesterol and Lipoproteins
Environmental Influences on Lipid Concentrations and Lipid Variability
Chronic Stress Mechanisms of Lipid Variability
Acute Stress Mechanisms of Lipid Variability
Interventions to Reduce Stress-Related Increases in Lipids
Clinical Implications of Variations in Lipids

Glossary

- Apolipoprotein* Proteins located on the surface of lipoproteins that transport proteins and bind to specialized enzymes.
- Cholesterol* A fat-soluble molecule in the body used to form cholic acid in the liver, steroid hormones in the gonads and adrenals, and used in the formation of cell membranes.
- Hemoconcentration* The generally transient and reversible filtration of fluid from the intravascular space.

Lipids

Chemical compounds in the body that are miscible with each other and which provide energy and a variety of intracellular functions. They include triglycerides, phospholipids, and cholesterol.

Lipoprotein

Large complexes of molecules that circulate and transport triglycerides, phospholipids, cholesterol, and proteins in the blood.

Lipid reactivity

Response of one or more of the lipids circulating in the blood to an external stimulus.

Structure and Function of Cholesterol and Lipoproteins

Lipoproteins are large, complex structures circulating in the blood that contain triglycerides, phospholipids, cholesterol, and proteins. Triglycerides are synthesized in the liver and adipose tissue, and are utilized as energy sources. Phospholipids are transported in lipoproteins, are formed in all cells of the body, and are particularly important in the formation of cellular membranes. Cholesterol, both exogenous and endogenous forms, also circulates in the lipoproteins and is used to form cholic acid in the liver. As with phospholipids, the most important function of cholesterol is the formation and permeability of

cell membranes. High circulating concentrations of low-density lipoprotein-cholesterol (LDLC) and low circulating concentrations of high-density lipoprotein-cholesterol (HDL) are associated with an increased risk of coronary heart disease (CHD).

Until recently, there has been a widely held understanding that blood cholesterol concentrations were relatively stable, showing only moderate elevations with aging, and transient but predictable elevations in triglycerides and related lipids postprandially, i.e. period of time after a meal. It is well documented that there are large inter- and intra-individual variations and fluctuations in plasma cholesterol, triglycerides, and LDLC concentrations. The variability within individuals is in the order of 10–20% over the course of a day or a week, and the degree of variability remains high even under reasonably standardized conditions.

Investigations of the factors responsible for such fluctuations are clinically relevant, because in order to make reasonable clinical decisions regarding assessment and treatment of hypercholesterolemia (condition describing a high concentration of cholesterol in the blood), an understanding of normal, biologically based variations in cholesterol concentrations are essential. As importantly, however, is the understanding of the causes of this variability in order to better understand the process of cholesterol regulation.

Environmental Influences on Lipid Concentrations and Lipid Variability

A variety of stimuli alter the blood concentrations of lipids. For example, numerous investigations have demonstrated that psychological stress reliably influences blood concentrations of cholesterol and lipoproteins. A separate and smaller literature has shown that individuals differ in their lipid responses to dietary challenge. Importantly, exaggerated lipid responsivity to diet is associated with an increased risk of CHD. To the extent that exaggerated lipid responses to environmental stimuli are atherogenic, investigation of the role of stress on lipid concentrations is of potential clinical importance. The task among behavioral scientists dedicated to investigating the phenomenon of stress-associated lipid changes is to delineate the potential mechanisms responsible for the effects, which will ultimately lead to either a confirmation or refutation of the notion that stress-associated lipid changes are atherogenic.

Several models have been proposed as potential pathways by which stress alters lipid concentrations in the blood; one such model is presented in [Figure 1](#). Although the pathways are not mutually exclusive

and are likely to be different under varying conditions of psychological stress, models such as these suggest ways of considering the current literature and point to obvious avenues for future research endeavors.

Chronic Stress Mechanisms of Lipid Variability

During chronically or pervasively stressful situations, cholesterol concentrations are elevated. A number of naturalistic studies have demonstrated that the stress associated with a major disaster or major stressor, such as the experience of earthquake, loss of job and income, and bereavement, can result in substantial increases in total cholesterol, LDLC, and triglycerides. Among better controlled laboratory studies of chronic stress, generally similar associations are noted between chronically stressful situations and elevated atherogenic lipids. Although there is not complete agreement, the preponderance of studies supports the notion that stress changes, or in some way is associated with, lipid concentrations in the blood. A meta-analysis of the bulk of the literature examining chronic or pervasive stressor effects on lipids demonstrates overall support for the notion that chronic stress is associated with elevated total cholesterol and LDLC concentrations ([Table 1](#)). Several prospective studies have further substantiated the notion that even when cholesterol concentrations are not elevated during periods of increased workload, there are still positive and significant associations between increased perceived stress and total cholesterol.

Behavioral Influences

Although it has been tempting to suggest that lipid changes are a result of stress-associated behavioral changes, such as diet and exercise modifications, which in turn increase lipid concentrations, data have not confirmed this as an adequate explanation. For example, a very early series of single case studies examined individuals while residing in a metabolic ward for periods of time ranging from 1 to 5 months. Diet, physical activity, exercise, and medication use were not only monitored, but actually closely regulated, and total cholesterol concentrations were measured frequently. Simultaneously, diaries were maintained periodically by both patients and the nursing staff, reporting on mood and perceived stress experiences. Total cholesterol levels were quite variable over time, despite the tightly controlled conditions and behaviors of the patients while in the ward. Moreover, total cholesterol fluctuations upwards were more prominent during times of self-reported perceived stress.

Figure 1 Potential pathways by which stress alters lipid concentrations in the blood (reprinted from Stoney & West (1997) *Lipids, personality and stress: Mechanisms and Modulators*. In: Hillbrand & Revben (eds) *Lipids, Health, and Behavior*, pp. 47–66. Washington, DC: American Psychological Association, with permission of the American Psychological Association). ETS, environmental tobacco smoke. Solid lines indicate that there is evidence for these pathways. Hashed lines indicate incomplete evidence for these hypothesized pathways.

Table 1 Meta-analysis on the effects of chronic stressors on lipid concentrations

Lipid variable	Number of studies	Unweighted effect size estimates (d)	P value
Total cholesterol	14	0.406	0.0001
LDLC	9	0.358	0.0001
Triglycerides	3	−0.014	0.05
Free fatty acids	5	0.071	0.05

LDLC, low-density lipoprotein-cholesterol.

More contemporary studies of much larger groups of men and women similarly found that the chronic stress-associated lipid elevations were maintained even after rigidly controlling variations in diet, exercise, sleep, medication use, and physical activity. For example, healthy men and women undergoing several weeks of predictable but potent work stress had elevated blood total cholesterol, LDLC, and triglycerides relative to lower work stress periods, independent of changes in diet, exercise, physical activity, medication use, and sleep patterns.

That said, in certain circumstances and for certain vulnerable individuals, stress is associated with changes in behavioral risk factors that can have important effects on cholesterol concentrations. For example, both chronically and acutely stressful situations cause some people to eat more, while others eat less. Among those who are so-called 'stress eaters', the increased eating may be, in part, a consequence of higher stress-related cortisol elevations. Importantly, at least one study has reported that those who report increasing caloric intake during stress have higher total cholesterol/HDLc during stress. However, even among this subset of vulnerable individuals, the increased lipid concentrations are small. Thus, although there may be a portion of individuals for whom lipid alterations during chronic stress are an indirect consequence of stress-induced changes in eating patterns, this mechanism likely does not explain the larger total cholesterol elevations that occur during stress among the majority of individuals.

Hormonal Influences

One way that stress might influence lipid concentrations is through stress-induced hormonal changes that affect lipid metabolism. For example, stress-induced sympathetic nervous system activity leads to concomitant increases in catecholamines (epinephrine and norepinephrine), glucocorticoids (cortisol), and free fatty acids. These increases have resultant effects on metabolism of the lipoproteins. For example, catecholamines can directly stimulate adipose tissue to release free fatty acids into circulation through the process of lipolysis. In particular, epinephrine induces the release of free fatty acids; during epinephrine infusion and mental stress, free fatty acid concentrations increase concomitantly. Epinephrine-induced increase in free fatty acids may be the result of increased blood flow through adipose tissue or stimulation of adipose- β 2 adrenoreceptors. In either case, the accumulation of circulating free fatty acids can trigger the production of triglyceride-rich, very low-density lipoprotein (VLDL) catabolism, which in turn will eventually result in increased concentrations

of circulating LDLc. Further, epinephrine will decrease VLDL secretion and increase LDLc uptake by stimulating α 1 adrenoreceptors.

Like epinephrine, norepinephrine influences lipoprotein metabolism. Increased norepinephrine activity stimulates adipose β adrenoreceptors. This may result in diminished lipoprotein lipase activity, a subsequent decline in triglyceride clearance, lower concentrations of HDL, and increasing levels of VLDL, intermediate-density lipoproteins (IDL) and LDL. Norepinephrine also decreases hepatic triglyceride lipase activity, which can increase plasma concentrations of both HDLC and triglyceride-risk lipoproteins.

Cortisol also has profound influences on the mobilization of lipids and lipid metabolism through activation of the hypothalamic-pituitary-adrenocortical (HPA) axis. Cortisol sensitizes adipose tissue to the lipolytic effects of catecholamines and increases concentrations of free fatty acids. Moreover, cortisol and free fatty acids stimulate the secretion of VLDL, increase the synthesis of hepatic triglycerides, inhibit insulin secretion, and increase insulin insensitivity in the tissues. Insulin regulates triglyceride synthesis and hepatic production of VLDL. Thus, the decreased activity of insulin during stress inhibits the regulation of triglycerides and the production of VLDL. Further, insulin resistance and increased levels of cortisol suppress hepatic LDL receptors and catabolism, thereby delaying LDL clearance. Cortisol also stimulates apolipoprotein B (apo B) secretion from cultured rat hepatocytes.

This pathway of stress-related, epinephrine-induced free fatty acid release from adipose tissue, enhanced hepatic cholesterol secretion, cortisol-associated lipolysis, and increased circulating LDLc concentrations has some empirical support. Chronic epinephrine infusions into cynomolgus monkeys produce significant total cholesterol concentration increases, and the same pattern has been noted among humans. Additional data regarding the effects of cortisol are also available. For example, several types of stressors simultaneously elevate LDLc, total cholesterol, apo B, insulin, and plasma cortisol. In some studies, the changes in cortisol positively predict changes in lipids. For example, a recent study reported that individuals with high cortisol stress recovery (reflecting higher cortisol stress responses) also had the highest LDLc and total cholesterol/HDLc ratios. Thus, the sympathetic-adrenal-medullary axis and the HPA axis are likely to play a key role in modulating lipid and lipoprotein metabolism during times of pervasive psychological stress. There are continuing efforts to delineate these pathways more definitively.

Acute Stress Mechanisms of Lipid Variability

The hypothesis that chronic stress affects lipids due to stress-induced hormonal changes has considerable appeal, but it is unlikely to account for the abundant additional data demonstrating rapid and transient increases in plasma cholesterol concentrations during acute psychological stress. For example, many laboratory-based investigations have shown that very short-term stressors, such as those that might occur over a period of several minutes to 1–2 h, can induce rapid and transient increases in blood concentrations of total cholesterol, LDLC, apo B, and triglycerides. A meta-analysis of these investigations has supported the notion that short-term stress reliably elevates total cholesterol, LDLC, triglycerides, and free fatty acids (Table 2). These elevations are clearly not a function of hormonally induced increased synthesis of lipids because the enhanced rate of lipoprotein entry into the circulation would simply take longer than the time period represented in these studies. Kinetic studies document that the manufacture of VLDL from fatty acids and subsequent conversion of LDL requires several hours to days to accomplish. Investigations of acute stress effects have also demonstrated little concordance between catecholamine and cortisol responses and acute changes in blood lipid concentrations. The effects of acute psychological stress on lipid concentrations are therefore likely to operate through a different mechanism or set of mechanisms.

Hemoconcentration Influences

Psychological stress causes a generally transient and rapid decline in the volume of blood plasma, with a resultant mild hemoconcentration of blood cells. This phenomenon is similar to the acute decreases in intravascular plasma volume that occur with postural changes, with a resultant posture-induced hemoconcentration of serum lipids. These plasma volume shifts can occur by increased red blood cell mass, alterations in kidney functioning, and/or through hemodynamically induced fluid shifts. Whatever the exact mechanism of the fluid volume shifts, it is clear that the resultant hemoconcentration leads

to higher lipid concentrations in the blood. Thus, the increased lipid concentrations in the blood during acute stress are likely to be partially, but not fully, accounted for by hemoconcentration. Generally speaking, during mild stressors that induce no hemodynamic or hormonal (e.g., catecholamine and blood pressure) changes, a significant portion of the generally small lipid increases might reasonably be accounted for by plasma volume shifts. However, during more substantial psychological stressors that are accompanied by alterations in catecholamines, blood pressure, and cortisol, increases in cholesterol and LDLC are generally more substantial. In some, but not all investigations, the lipid (generally total cholesterol and triglyceride) and lipoprotein (LDLC) elevations remain significant even after correction for transvascular plasma volume shifts. For those investigations that do not show significant lipid elevations after correction for plasma volume shifts, it is possible that the failure to retain significance is related to decreased power in combination with modest effect sizes. The fact that some lipoproteins are consistently elevated during stress (e.g., LDLC) and others are not (e.g., HDLC) suggests that transvascular shifts cannot account for all of the stress-related changes observed, because otherwise all lipid particles would show the same pattern of response.

Metabolic Influences

This state of affairs has led to the speculation that there may be a metabolic explanation for the acute stress-induced elevation in blood lipid concentrations. For example, stress-associated elevations in lipids and lipoproteins may be due to metabolic effects of sympathetic activation. Pharmacologic blockade of sympathetic activation with a nonselective adrenoceptor antagonist among men completing several acutely challenging tasks blocked stress-associated increases in free fatty acids and triglycerides, but not total cholesterol or LDLC. These data add support to the notion that different lipids are likely influenced by environmental and psychological factors through different mechanisms.

Stoney et al. have reasoned that if stress does have a direct influence on certain blood lipid levels, that

Table 2 Meta-analysis on the effects of acute stressors on lipid concentrations

Lipid variable	Number of studies	Unweighted effect size estimate (<i>d</i>)	<i>P</i> value
Total cholesterol	25	0.306	0.0001
LDLC	14	0.291	0.0002
Triglycerides	24	0.341	0.0001
Free fatty acids	37	0.717	0.0001

LDLC, low-density lipoprotein-cholesterol.

this may be reflected in the efficiency with which individuals metabolize a high-fat meal during stress. In a test of this hypothesis, a standard intravenous load of intralipid (a triglyceride-rich product) was administered to a group of middle-aged men and women under a condition of psychological stress, and then again during a condition of no psychological stress. In this test, which is similar conceptually to a glucose tolerance test, a triglyceride determination was made and then a standard bolus of intralipid was administered. Serial triglyceride determinations were then made over time, and the disappearance rate constant (K_2) was calculated. Thus, K_2 defines the clearance rate of the exogenous fat solution, with a higher K_2 value indicating a more efficient clearance of triglycerides from the circulation. When administering this test to a group of healthy individuals, Stoney et al. found that K_2 values declined significantly during stress, in relation to a nonstress period, showing that the increases in lipids during acute stress were due to altered clearance rates. They also found that individuals who were slow to clear a triglyceride load were more hostile than those who were more efficient at clearing the triglyceride load imposed. These data are the most compelling to date to indicate that blood lipid concentrations are altered during psychological stress because of altered triglyceride metabolism and that this may be related to an increased risk of CHD.

Interventions to Reduce Stress-Related Increases in Lipids

Outside of altering health behaviors or broad lifestyle changes, very few clinical interventions have been tested as potential means to reduce the stress-associated elevations in lipids. Stress reduction techniques such as relaxation, meditation, and self-monitoring likely have effects on both behavioral risk factors and lipid levels. For example, individuals with highly demanding jobs and who spent 3 weeks away from their job responsibilities and in a spa had more substantial decreases in LDLC and LDL/HDL ratio than did those who also spent time in a spa but who had less demanding occupations. However, no studies have explicitly tested the mechanisms by which reductions in perceived stress related to reductions in lipid and lipoprotein concentrations.

Clinical Implications of Variations in Lipids

There is little doubt about the presence of a direct relationship between blood cholesterol concentrations and the development and initiation of cardiovascular disease. For example, chronically elevated LDLC is associated with an elevated incidence of

coronary artery disease (CAD), and lowering LDLC concentrations produces a regression of coronary atherosclerosis and coronary artery events in some individuals. Elevations in triglycerides and low levels of HDLC are also correlated positively with both CAD and CHD although it is not clear to what degree lowering triglyceride or raising HDLC levels also results in a diminished risk for cardiovascular disease.

Although there are no prospective investigations of the clinical relevance of stress-associated elevations in lipids, data from several cross-sectional investigations are informative. A number of investigations have demonstrated that healthy individuals at an elevated risk for the future development of cardiovascular disease have more profound short-term elevations in blood lipid concentrations during stress, relative to a nonstress period. For example, men, postmenopausal women, and healthy young offspring of parents with documented myocardial infarction all have greater elevations in total cholesterol and LDLC during acute psychological stress, relative to women, age-matched premenopausal women, and healthy offspring of parents with no cardiovascular disease, respectively. Additionally, psychosocial factors that have been shown to be related independently to CHD risk, such as hostility and anxiety, are also associated with total cholesterol and LDLC concentrations. Future cross-sectional and prospective investigations examining the extent to which stress-induced elevations in lipid concentrations are atherogenic are warranted.

Glossary

*Myalgic
encephalo-
myelitis (ME)*

Term invented to describe an outbreak of unexplained illness that affected the staff of the Royal Free Hospital in 1955. It has become linked to chronic fatigue syndrome in the last 20 or more years. Because encephalomyelitis is a specific pathological process not found in these patients, the term is avoided in the scientific literature.

Neurasthenia

A term introduced to medicine in 1869 to describe an illness characterized by chronic physical and mental exhaustion after minimal effort and accompanied by numerous somatic symptoms, a precursor for modern chronic fatigue syndrome. Originally thought to be an organic disease of the central nervous system caused by depletion of the energy supply to the brain resulting from such insults as overwork or infection, it was later seen as a psychological condition linked to depression and anxiety. Now an archaic term, although retained in the latest *International Classification of Diseases* (ICD-10).

*Postviral
fatigue
syndrome
(PVFS)*

A term used to describe chronic fatigue syndrome apparently triggered by a viral infection. Because of the frequency of viral infections and the lack of any compelling evidence implicating viral infection in the persistence of most cases of CFS, the term is to be avoided unless there is clear-cut evidence of a relevant infective trigger.

Somatization

A condition in which the patient presents with a physical symptom that is attributed to a physical disease but is more likely to be associated with depression or anxiety.

Chronic fatigue syndrome (CFS) is an operationally defined syndrome characterized by a minimum of 6 months of severe physical and mental fatigue and fatigability, made worse by exertion. Other symptoms such as muscle pain, sleep disorder, and mood disturbance are common. [Table 1](#) lists the current consensus criteria, although the Centers for Disease Control (CDC) identified ambiguities in these criteria, and more recommendations for their resolution, in 2003 (Reeves et al, 2003). Other common causes of chronic fatigue must be considered before the diagnosis can be made.

Historical Aspects

The term chronic fatigue syndrome (CFS) is a relatively recent arrival on the medical scene, but it is not a new illness. The condition known to the Victorians as neurasthenia is clearly its forerunner, not just in terms of symptoms, but presumed etiologies, treatments, and much else. As neurasthenia gradually shifted from a physical to a psychological etiology, its popularity declined, and the diagnosis had effectively vanished by World War II, except in parts of Asia. Chronic fatigue syndrome appeared in internal medicine in the 1980s in response to a variety of events, including renewed claims to have found a physical, infective cause for the symptoms, a series of well-publicized epidemic outbreaks, and the general change in doctor–patient relationships during this period. The term CFS and its variants are now widely used in the English-speaking and Scandinavian world, but not elsewhere.

Symptomatology

The hallmark of CFS is severe fatigability, of both mental and physical functions, after minimal exertion. It is accompanied by other common symptoms, chiefly muscle pain, sleep disorder, and mood disturbance. Some sufferers complain of symptoms affecting most bodily functions. CFS should not be diagnosed without some complaints of physical fatigue and fatigability (reduced functional capacity, symptoms after minor exertion, postexertional myalgia, and others)

Table 1 Consensus operational criteria for chronic fatigue syndrome^a**Patients must have the following:****1. Chronic fatigue that**

Is of new onset (not lifelong)

Has lasted at least 6 months

Has resulted in substantial functional impairment (occupational, social, or personal activities)

Is not substantially alleviated by rest

2. At least four of the following symptoms for at least 6 months

Memory or concentration impairment

Sore throat

Tender lymph nodes

Muscle or multijoint pain

Headaches

Unrefreshing sleep

Postexertional malaise lasting > 24 h

3. No medical illness explaining the symptoms**4. No diagnosis of**

Psychosis (schizophrenia, mania or psychotic depression)

Eating disorder (anorexia nervosa, bulimia nervosa)

Dementia

Alcohol or substance abuse

Severe obesity (body mass index > 45)

^aData from Fukuda et al. (1994). *Annals of Internal Medicine* 121, 953–959.

and mental fatigue and fatigability (poor concentration, symptoms made worse by mental effort, subjective memory disturbances, etc.). Because there are many causes of chronic fatigue and fatigability, it is essential that an appropriate medical evaluation is undertaken before diagnosing CFS, including physical examination, mental state examination, and simple investigations.

Epidemiology

Chronic fatigue is one of the commonest somatic symptoms – between 20 and 30% of most populations studied report symptoms such as exhaustion and feeling tired all the time. Some of these are short-term complaints, but around 10% of those attending general practice will complain of chronic fatigue sufficient to interfere with their lifestyle and lasting at least 6 months. Operationally defined CFS is less common, ranging from 0.1 to 3% depending on the definition used, with the best estimates suggesting that approximately 1% of primary care attendees fulfill the diagnostic criteria. Even when those with comorbid psychiatric disorders are excluded, a reasonable estimate of prevalence of pure CFS is approximately 0.5%. Few of these subjects will use a term such as CFS, myalgic encephalomyelitis (ME), or its variants to describe the illness. Population surveys have found similar prevalence of CFS in people

of different socioeconomic status. Women are at higher risk than men (relative risk 1.3–1.7, depending on the diagnostic criteria used), while studies of ethnicity suggest that White individuals have a lower risk of CFS compared with Latinos, African Americans, and Native Americans. Different characteristics have been reported in clinic populations (e.g., an excess of White professionals), almost certainly because of biases in referral patterns.

An operational definition should not be taken as endorsing the concept of CFS as a discrete disorder – in fact, epidemiological research suggests that it is not, and is best viewed as the extreme end of a normally distributed spectrum of fatigability, much in the same way as high blood pressure is not a discrete disorder distinguishable from moderate blood pressure.

While it is unlikely that CFS is a single illness, efforts to define valid subgroups by symptom profile or etiological factors have not yet been particularly fruitful. Dividing those with an abrupt onset to symptoms from those with a more insidious origin seems to have some merit, the former having a more favorable prognosis. Differences also exist between the minority of cases with long illness histories, severe disability, and multiple symptoms, who show overlap with the concept of somatization disorder, and the larger group with less disability, fewer symptoms, and shorter illness durations.

Another area of confusion is the relationship between CFS and other medically unexplained syndromes. Especially in specialist practice, there is considerable overlap between CFS and the condition recognized by rheumatologists as fibromyalgia. It is likely that the boundaries between CFS and other unexplained and/or controversial syndromes such as irritable bowel syndrome and multiple chemical sensitivity are similarly fuzzy. Another area of overlap is between chronic fatigue and chronic pain. The similarities are many: the increased rates of affective and somatic symptoms, the role of avoidance behavior in sustaining symptoms, the role of physical factors as precipitants, the need for rehabilitation rather than cure, and the role of social and economic factors in perpetuating disability and causing conflict both with and between doctors.

Etiology

Biological Factors

Genetics Studies suggest that there is a genetic propensity to suffer from chronic fatigue, with the concordance between monozygotic twins more than twice that of dizygotic twins. Multivariate modeling suggests that part of this vulnerability is conferred

through the genetic tendency to suffer from anxiety or depression, but that part is independent of psychiatric disorder.

Muscle Although muscle pain and complaints of muscle fatigability are common, there is little objective evidence that symptoms have a primary neuromuscular origin. Most studies of neurophysiological function have been normal, particularly once the secondary effects of inactivity are taken into account. There may be a small group whose symptoms are related to primary muscle dysfunction, but given the importance of mental fatigue and fatigability, central rather than peripheral explanations are more likely to be relevant for most patients.

Viruses While it is common for patients to date the onset of their symptoms to common viral infections, a controlled prospective study found that subjects who consulted their physician with viral symptoms showed the same rate of subsequent chronic fatigue as those consulting for other reasons. There is, however, consistent evidence that certain infective agents causing severe illness, such as the Epstein–Barr virus (EBV), viral hepatitis, Q fever, or viral meningitis, are associated with prolonged fatigue reactions (Table 2). Several factors increase the risk of developing prolonged fatigue after such infections. These include pre-existing fatigue, older age, female gender, previous psychiatric disorder, and the response to symptoms (including a prolonged convalescence from illness and oversolicitous social support). The response of the doctor may be important, too: provision of a sick note and an unclear diagnosis have both been associated with the development of CFS.

Neurochemistry Early studies in normal subjects showed that fatigue after exercise was associated with a rise in plasma levels of tryptophan and, theoretically, increased brain serotonin (5-HT) production. In CFS, increased cerebrospinal fluid (CSF) levels of 5-HIAA relative to controls suggested increased turnover of

5-HT in the CNS (brain and spinal cord). Many studies have used direct challenges of brain serotonergic receptors, measuring neuroendocrine responses as indices of the functional status of these receptors. These have generally revealed enhanced responses, suggesting increased serotonergic neurotransmission. These findings are important when set in the context of similar studies in major depression that reveal the opposite change: reduced serotonergic function. The importance of these changes is not yet understood. It is possible that they are of physiological significance, since 5-HT is known to be important in the physiological control of sleep, appetite, and mood. In parallel with the opposite 5-HT changes, these features are disturbed in opposite directions in classic endogenous depression (insomnia, anorexia, agitation) and CFS (hypersomnia, hyperphagia, and retardation). Given what we know about brain physiology, it is also conceivable that these changes could be secondary to low cortisol levels or the effects of inactivity, sleep disturbance, or disruption of circadian rhythms.

Recent advances in neurochemical imaging have allowed direct visualization of cerebral serotonin receptors in CFS. Early studies in CFS report a reduction in 5-HT_{1A} receptor binding throughout the brain, most markedly in the hippocampi bilaterally (Figure 1), and reduced serotonin transporter binding in the rostral anterior cingulate gyrus. It has been suggested that these findings represent receptor down-regulation in the face of chronically raised synaptic serotonin levels, but other explanations are also possible, including a longstanding effect of prior depressive illness.

Although there have been individual studies of other neurotransmitter dysfunction in CFS, further study is needed before drawing any conclusions.

Neuroendocrine Dysfunction Abnormal function of the hypothalamic-pituitary-adrenocortical (HPA) axis (Figure 2) has been demonstrated in several centers. Most, but not all, of the better-quality studies using serial samples of blood or saliva, or 24-h urinary collections, have found reduced basal cortisol output, again the reverse of that seen in major depression. Studies of the circadian rhythm suggest a blunted early morning rise of corticotropin (ACTH). This is paralleled by the findings of an impaired ACTH or cortisol response to a variety of challenges to the HPA axis, including CRH, arginine vasopressin (AVP), Synacthen (1–24 adrenocorticotropin), insulin, naloxone, exercise, social stress, and awakening. There is also evidence of heightened negative feedback and glucocorticoid receptor function. However, there is no evidence for a unique or uniform dysfunction of the HPA axis. Given the many factors that may

Table 2 Fatigue following severe infections

	<i>Rate of persistent fatigue 6 months after diagnosis (%)</i>
Viral meningitis	25
Epstein–Barr virus glandular fever	12–16
Viral hepatitis	20
Q fever	42 ^a

Baseline risk	1

^aThere were also very high rates (26%) in controls in this study.

Figure 1 Cerebral 5-HT_{1A} receptor binding in CFS, measured using positron emission tomography and [¹¹C]WAY-100635. On the left, the statistical parametric mapping analysis (using a threshold of $P < 0.01$) is shown in three dimensions, revealing a widespread reduction in 5-HT_{1A} receptor binding in CFS versus controls throughout the brain. On the right, results using a stricter threshold ($P < 0.001$) are projected onto a standardized T1-weighted magnetic resonance image, showing bilateral reductions in 5-HT_{1A} receptor binding centered on the hippocampus. From Cleare, A. J., Messa, C., Rabiner, E. and Grasby, P. (2005). Brain 5-HT_{1A} receptor binding in chronic fatigue syndrome measured using positron emission tomography and [¹¹C]WAY-100635. *Biological Psychiatry* **57**, 239–246.

Figure 2 Components of the hypothalamic-pituitary-adrenocortical (HPA) axis and directions of positive and negative feedback loops. Abbreviations: CRH, corticotropin-releasing hormone; ACTH, corticotropin; AVP, arginine vasopressin; MR, mineralocorticoid receptors; GR, glucocorticoid receptors. See Table 4.

impinge on the HPA axis in CFS, such as inactivity, sleep disturbance, psychiatric comorbidity, medication, and ongoing stress, it seems likely that HPA axis disturbance in CFS is heterogeneous and of multifactorial etiology.

One issue with all of the above studies is that they were largely undertaken on samples of patients that had been ill for several years, and the relevance of these

HPA axis changes to the onset of illness is unknown. Prospective studies of groups at high risk of developing chronic fatigue (post-EBV infection and postsurgery) have found that the development of fatigue 6 months later was not associated with any HPA axis changes.

Thus, at present it appears that HPA axis changes are not important during the early stages of the genesis of fatiguing illnesses. However, the low cortisol levels that may develop at a later stage of the illness do appear to be of clinical relevance, since their reversal using supplementation with a low dose of hydrocortisone can improve fatigue in some patients. Also, there is now evidence that HPA axis changes can be reversed by modifying behavioral features of the illness such as inactivity, deconditioning, and sleep disturbance, using cognitive behavioral therapy.

Consistent evidence for other disruption of other neuroendocrine systems is lacking.

Neuroimaging The literature to date on CFS has been conflicting. Though some early studies did suggest that there was reduced blood flow to many areas of the brain, most notably the brain stem, more methodologically rigorous studies, particularly those in which comorbid depression was controlled for, suggested that there was no decreased blood flow and some subcortical areas of increased flow. Furthermore, a study that compared 22 pairs of monozygotic twins discordant for CFS found no alterations in regional cerebral blood flow.

Structurally, some studies have found an increased number of white matter hyperintensities, something nonspecific and also found in mood disorders. Some

findings of lateral ventricular enlargement, global loss of gray matter, and reduced hippocampal neuronal density have been reported, but there are as yet no replicated findings.

Finally, functional MRI studies are beginning to identify the neural correlates of the symptom of fatigue; these may enhance our understanding of the brain mechanisms underlying the sense of effort.

Immunology Initial views of CFS emphasized immunological changes as an inherent part of the syndrome. Subsequent studies have given conflicting results – normal, increased, or decreased cell-mediated and humoral immune markers. The most frequent finding is a mild immune activation, but it is unclear whether this is secondary to the decreased cortisol tone (see previous discussion) or frequent mood disorder found in CFS. There is also some evidence of a shift toward a Th2-type immune response. However, there has been little evidence of a relationship between immune dysfunction and clinical parameters or outcome, and no evidence at all of any clinical immunological problems. Likewise, although abnormal cytokine release in response to antigen challenge is a tempting model for CFS, this would have to be centrally mediated, and has not been proven.

Autonomic nervous system Several studies have investigated the possible role of the autonomic nervous system in CFS. A number of studies have found an increased rate of neurally mediated hypotension, while others have found evidence for sympathetic overactivity and/or parasympathetic underactivity. Whether these are causal factors in CFS remains under debate since both anxiety and prolonged inactivity are associated with similar changes.

Psychological Factors

Life events The literature regarding the effects of life events on CFS is still conflicting. It is clear that, as in other conditions, adverse life events in CFS are strongly associated with the development of psychological disorders. There is also some evidence that negative life events may be related to the development of, and chronicity of, fatigue, with the best evidence suggesting an excess of negative life events in the 12 months prior to the onset of CFS. Positive life events may be protective.

Several specific stresses have been studied: around one-third of patients suffer from significant fatigue following major surgical operations, while the overtraining syndrome (renamed the underperformance syndrome [UPS]) afflicts athletes who engage in periods of excessive exercise and bears some similarities with the symptoms of CFS. Others have studied

fatigue syndromes occurring during cancer treatment or α -interferon administration. These conditions share with CFS the interaction of psychological and physiological factors in producing the final clinical picture.

Psychiatric disorder The relationship between psychiatric disorder and CFS remains controversial, but there is no doubt that such a relationship exists. Exact rates of psychiatric disorder vary from study to study, but usually between one-half and two-thirds of clinical samples fulfill criteria for psychiatric disorder as well as CFS. The greater the number of symptoms and the greater the disability, the greater the chance of psychiatric disorder. Importantly, a series of controlled studies have shown that these rates are too high to be explained simply as a reaction to physical disability (Table 3), though clearly this is part of the explanation. Other possible explanations include misdiagnosis, a neurobiological origin common to CFS and psychiatric disorder, and the overlap between the criteria used to diagnosis CFS and the common psychiatric disorders. No study has ever reported complete congruence between CFS and psychiatric disorder. Furthermore, factor analytic studies

Table 3 Studies comparing prevalence of psychiatric disorder in CFS with prevalence in medically ill controls

<i>Control group</i>	<i>Prevalence of psychiatric disorder (%)</i>		<i>Relative risk of psychiatric disorder in CFS</i>
	<i>CFS</i>	<i>Controls</i>	
Neuromuscular diseases	72	36	2.0
Myopathies	45	6	7.5
Rheumatoid arthritis	41	13	3.3
Multiple sclerosis	23	8	2.9
Multiple sclerosis	45	16	2.8

Table 4 Sites of possible HPA axis abnormalities in CFS shown in Figure 2

<i>Level (Figure 2)</i>	<i>Finding</i>
1	Hippocampal atrophy
1	Impaired rate-sensitive negative feedback
1	Reduced suprahypothalamic drive to HPA axis
2, 3	Enhanced negative feedback
2	Impaired CRH and/or AVP release from hypothalamus
3	Impaired pituitary response to CRH
4	Blunted adrenal cortex response to ACTH
4	Adrenal gland atrophy
1–4	Impaired HPA response to a variety of stressors
5	Low basal cortisol

of postviral cohorts support the existence of fatigue-like symptoms at least partially separate from anxiety and depression symptoms.

The commonest psychiatric disorder reported in studies of CFS is depression (perhaps because of the considerable overlap of operational criteria), which has led to a relative neglect of anxiety disorders. However, in some respects CFS shares more similarities with anxiety than with depression, particularly in terms of neuroendocrine dysfunction, the role of fear and avoidance behavior, and treatment response.

The role of personality remains unclear, with the literature split as to whether certain personality traits like perfectionism predispose an individual to CFS.

Neuropsychological function CFS patients frequently complain of considerable difficulties with memory, attention, and concentration. However, the results of neuropsychological testing in CFS are inconsistent. In general, the objective findings do not reflect the severity of the subjective complaints encountered. Some changes may be explained by depression, anxiety, and/or sleep disturbance. There is evidence of deficits in higher and more complex cerebral function, such as selective attention. The selection of comparison groups is important; in a twin study, although CFS patients showed reduced performance on timed cognitive tasks, so did their nonfatigued twins. Nevertheless, it is plausible that sufferers find everyday tasks that require increased cognitive resources to be difficult, and that although they are able to perform reasonably well on such tasks, it is at the price of increased mental effort. Physical exercise also worsens effortful cognitive processing in CFS, suggesting that a disorder of the sense of effort lies at the heart of CFS.

Cognitive-behavioral factors The cognitive-behavioral model distinguishes factors that may have precipitated chronic fatigue from secondary factors thought to maintain fatigue and disability. The latter include the following:

1. Effects of inactivity: prolonged rest is an effective strategy in the short term but counterproductive in the medium and long term. With the passage of time, more symptoms and greater fatigue occur at progressively lower levels of exertion. Inactivity therefore sustains symptoms and increases sensitivity to them.

2. Inconsistent activity: many sufferers are not persistently inactive; instead, excessive or prolonged rest is followed by a burst of activity that is out of proportion to the preceding level of inactivity. This pattern may also be reinforced by the sense of frustration often encountered in sufferers, and perhaps also by

pre-existing personality and lifestyle factors. This sudden increase in activity culminates in exhaustion, for which the inevitable response is further rest. This stop-start pattern means that while extremes of disability are often avoided, sufferers are unable to build up a sustained level of recovery. This pattern may underlie the characteristic complaint of CFS sufferers of delayed fatigue and myalgia, well-recognized physiological phenomena that occur between 24 and 48 h after any exertion in excess of a person's current (and not previous) fitness.

3. Illness beliefs and fears about symptoms: these can influence disability, mood, and behavior in any illness. In CFS, unhelpful and inaccurate illness beliefs, reinforced by ill-informed media coverage, include the fear that any activity that causes an increase in fatigue is damaging or impossible; that doing too much causes permanent muscle damage; that CFS is due to a persistent virus or progressive immune disorder; that CFS is irreversible or untreatable; and that rest is the only remedy. Research suggests that the tendency of CFS patients under specialist care to ascribe their illness to a predominantly biological cause is not the issue – what predicts the outcome is how the meaning given to symptoms influences the choice of strategies to deal with such symptoms.

4. Symptom focusing: many patients have come to rely on day-to-day monitoring of their own symptoms as the best method of determining activity levels hour by hour. Concern about the meaning and significance of symptoms, interpreted as warning signals or relapses, is heightened by the unpredictable nature of CFS. Increased concern leads to heightened awareness, selective attention, and body watching, which can then intensify both the experience and perceived frequency of symptoms. A vicious circle is set up, thereby confirming illness beliefs and reinforcing disability.

Social Factors

Social influences on CFS operate in two arenas. The first is on the micro level. Social support influences the outcome of most conditions, and CFS is unlikely to prove an exception. One recent study suggested that certain forms of support can be helpful, but others can be detrimental. Oversolicitous support from a spouse or partner may, as in chronic pain, have a paradoxically adverse effect on outcome.

CFS also exists in the macro arena. It has become a cause célèbre, one likely to excite passion from many quarters. This reflects the difficulties that patients and doctors have in dealing with illnesses of uncertain etiology that cannot be easily pigeonholed. It also reflects the changing nature of the doctor-patient relationship and the increasing reluctance of many

people to accept what they see as inadequate or dismissive attitudes from doctors.

Interaction of Predisposing, Precipitating, and Perpetuating Factors

An alternative method of dissecting the various components of pathophysiology in CFS is to identify areas where factors may act as risk factors, triggers, and perpetuating factors. [Figure 3](#) shows the preceding factors separated in such a schema.

Treatment

Pharmacotherapy

Antidepressants Two placebo-controlled studies of fluoxetine in CFS showed divergent results, one indicating no benefit, even in depressed CFS patients, the other showing mild benefit to both fatigue and depression. Two studies of monoamine oxidase inhibitors (phenelzine and moclobemide) also showed mild benefit, primarily on symptoms rather than disability. Low dose tricyclics are helpful if pain or insomnia predominate, but there are no randomized controlled trials specifically in CFS.

Corticosteroids Because of the finding of reduced cortisol levels, two studies investigated a replacement strategy using hydrocortisone (cortisol). A full replacement dose (30 mg daily) produced mild benefit but also endogenous adrenal suppression. Smaller doses (5–10 mg daily) produced large reductions in fatigue in about 28% compared to 9% in the placebo group, without adrenal suppression. Potential side effects probably preclude such strategies as routine treatments but suggest that low cortisol levels may be a significant perpetuating factor in fatigue chronicity. Three randomized controlled trials used the mineralocorticoid fludrocortisone (one in combination with hydrocortisone) in order to treat a presumed autoimmune disorder and found no benefits.

Other Claims have been made for several other treatments, including magnesium supplements, oil of evening primrose oil, nicotinamide adenine dinucleotide and immunotherapy. None have yet passed the tests of replication or safety.

Graded Exercise Therapy

Given the perpetuating effects of inactivity and chronic fatigue, graded exercise is an obvious treatment for CFS. Research has shown that, providing account is taken of the level of deconditioning, CFS patients can perform graded exercise without adverse effects. Clinical trials have confirmed the considerable

benefits. However, improvement is not related to measures of fitness, suggesting that the benefits of exercise are more behavioral than physiological and may reflect increased confidence and decreased avoidance behavior. Nevertheless, many patients are reluctant to engage in such programs, usually because of fears of possible adverse consequences.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is a promising line of treatment. It encourages a collaborative approach to treatment, emphasizes the importance of engagement, and has lower dropout rates than those encountered in simple exercise programs. Treatment depends upon challenging some of the unhelpful illness beliefs encountered in some specialist clinics, overcoming behavioral avoidance by encouraging consistent, modest activity followed by graded increases, and looking at cognitive factors associated with predisposition and relapse (previous discussion). Controlled trials confirm the benefits of treatment in specialist centers: in one study, two-thirds of patients had a good outcome 6 months after the end of treatment, compared to one in five receiving relaxation as a control for nonspecific effects of treatment. One problem, however, has been the shortage of skilled therapists. There is now evidence that less specialized therapists (but not, regrettably, general practitioners) can also be trained to deliver effective CBT for CFS. Good outcome is associated with altered beliefs about the relative merits of rest versus exercise. Benefits are largely maintained at 5-year follow-up. CBT may also reverse some of the HPA axis changes seen in CFS.

Prognosis

The prognosis of patients attending specialist clinics and not receiving rehabilitation is poor. A systematic review of the long-term prognosis of specialist clinic attenders, undertaken prior to the introduction of effective rehabilitation strategies, found that children had better outcomes than adults: 54–94% of children showed definite improvement in symptoms, whereas 20–50% of adults showed some improvement in the medium term and only 6% returned to premorbid levels of functioning. Factors associated with a poor prognosis are a longer duration of illness, fatigue severity, comorbid depression and anxiety, and holding an exclusively physical attribution for CFS. This latter factor is not a problem *per se*, but is probably associated with continuing behavioral avoidance and firm beliefs about the adverse effects of activity. Given that most patients do not reach a specialist clinic until they have been ill for some years, it may

Predisposing factors (risk factors) in fatigue generation:

Female gender
Past psychological illness
Somatic attributional style
Illness in close family members
Childhood experiences
History of fatigue
History of other medically unexplained symptoms
Genetic

Precipitating factors (triggers) in fatigue generation:

Serious infective illness (EBV, Q fever, viral meningitis, viral hepatitis)
Life events
Operative stress
Overtraining
Depression/anxiety
Cancer
Physical trauma?
Head injury?

ACUTE OR
SUBACUTE FATIGUE

Perpetuating factors:

Response to fatigue: Prolonged bed rest or time off work
Fixed somatic attribution of cause
Demoralization, depression, anxiety

Effects of inactivity: Fatigue
Physical deconditioning

Response of doctor: Issuing sick note
Imprecise diagnosis

Behavioral factors: Use of avoidance as coping strategy

Cognitive factors: Loss of control
Belief that exercise will cause damage or worsen fatigue

Biological factors: Reduced cortisol levels
Hypothalamic disturbance
Circadian rhythm disruption or desynchronization
Altered central 5-HT receptor sensitivity
Autonomic disturbances

Sleep: Insomnia, hypersomnia, or poor sleep efficiency

Social factors: Reinforcement by others
Work-related problems
Lack of social support

CHRONIC FATIGUE OR
CHRONIC FATIGUE SYNDROME

Figure 3 Various potential factors in the generation of acute, subacute, and chronic fatigue. The model separates those that are thought to be risk factors or triggers and those that may be responsible for fatigue perpetuation in CFS. Many of the latter may be amenable to treatment. Factors interact substantially and may be more important in some patients than in others.

also simply be that chronicity predicts chronicity. There is insufficient knowledge about the prognosis of the larger problem of CFS in the community and primary care, but it is likely to be more optimistic. Adequate treatment improves prognosis.

Synthesis

One theme that emerges from the literature of all the fatigue syndromes is the possibility of a general disorder of perception, perhaps of both symptoms and disability. At the heart of this misperception lies the sense of effort. CFS patients clearly experience increased effort in everyday physical and mental tasks, reflected in sense of painful muscle exertion and painful cognitive processing. This increased effort is the not the result of increased neuromuscular or metabolic demands (a Victorian concept), nor does it result in any substantial decline in actual muscle or cognitive performance. The result is a mismatch between patients' evaluation of their physical and mental functioning and the external evidence of any consistent deficits. The basis of this disorder of effort must remain speculative, particularly since the perception of effort is a complex topic. It is possible that it is because the sufferer needs to devote more attention, or even energy, to processes that the rest of us find automatic, be it muscular exertion or mental concentration. Why that should be remains unclear.

From this fundamental problem come other problems identified in CFS, such as increased symptom monitoring, decreased tolerance, and increased anxiety. These are not unique to CFS and have also been described, for example, in fibromyalgia and irritable bowel syndrome. Thus, some centrally mediated disorder of perception of information may underlie the experience of fatigue syndromes and explain the widespread discrepancies between the intensity of symptoms and disability and objective testing of a number of different parameters, both physiological and neuropsychological.

CFS continues to present to clinicians and is associated with high levels of disability and distress. Yet it is an elusive and awkward issue for modern scientific medicine, particularly in the social context in which medicine is now practiced. As outlined previously, the fullest understanding at the present time involves using a multidimensional approach in which due attention is given to both physical and psychological factors and to their interaction. Unitary models of the condition have little scientific basis at present; as with other multifactorial conditions, it is important to consider the roles of predisposing, precipitating, and perpetuating factors. For now, the most effective interventions are aimed at possible perpetuating

factors. As more is understood in the future, it is possible that there will be greater potential for targeting risk factors, the prevention of CFS after identified triggers, and the modification of the biological processes underlying fatigue.

Stress and the Immune System
Glucocorticoid Receptors Resistance Model
Clinical Implications

Glossary

<i>Anti-depressants</i>	Drugs used to treat depression. Their main mode of action is presumed to be related to elevation of synaptic monoamine levels.
<i>Cytokines</i>	Proteins that are secreted from immunocompetent cells. They act as ligands to transmembrane receptors on immune cells and other tissues to modulate the immune response. Examples are interleukins or tumor necrosis factor.
<i>Glucocorticoid receptors (GRs)</i>	Intracellular receptors with high affinity to glucocorticoids. They belong to the superfamily of nuclear steroid receptors such as thyroid hormone, estrogen, and testosterone. After the glucocorticoid binds to its receptor, the newly formed glucocorticoid–receptor complex translocates into the cell nucleus, where it stimulates or inhibits transcription of genes. Among other things, it modulates transcription of cytokines.
<i>Leukocytes</i>	White blood cells, consisting of granulocytes, lymphocytes, and monocytes. They are immunocompetent cells that act as a defense against infection and progression of malignant cells.
<i>Receptor sensitivity</i>	The responsiveness of a cellular system to a ligand. It reflects the binding of the ligand to its receptor and the effectiveness of the signal transduction.

Stress and the Immune System

Stress is an unavoidable part of human life. Be it infection, physical trauma, or social stress, the body handles the challenges of stress in similar ways, by activating the hypothalamic-pituitary-adrenocortical (HPA) axis and the autonomic sympathetic nervous system. This activation leads to increased levels of circulating glucocorticoids and adrenaline. Leukocytes have glucocorticoid and adrenergic receptors and respond to their signal. The leukocytes change positions (marginate to blood vessel walls or redistribute to lymph nodes and to the skin) and secrete pro-inflammatory cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor- α (TNF- α). If an immunological challenge is not met, this process ends after 3 to 5 days. Glucocorticoids that are involved in activating this pro-inflammatory process also serve as the signal to stop it. They exert this effect via two pathways: negative feedback at the HPA axis and direct immunosuppressive effect on leukocytes.

Social stress is frequently a chronic experience, taking place day after day for weeks, months, or even years. Examples are work overload, unemployment, living in a violent neighborhood, and caring for a loved one with a chronic disease. Our understanding of the influence of chronic social stress on the immune system has changed over the years. Initially, an immunosuppressive model was suggested. Individuals exposed to chronic social stress were reported to be more prone to infectious or neoplastic diseases. The explanation was that excess glucocorticoid levels cause an immunosuppressive state, similar to that found in subjects taking high doses of steroids. A limitation of that model was that it did not explain the observation that people under chronic stress are also more susceptible to allergic, autoimmune, and cardiovascular diseases, that is, disorders related to overactive immunity. That led to a model that emphasizes dysregulation of the immune system, in which

some functions are dampened while others are enhanced. A proposed explanation involves different effects of chronic stress on two subtypes of lymphocytes, T helper 1 (TH1) and T helper 2 (TH2). TH1 secretes cytokines (IL-2 and interferon- γ) that promote function of natural killer cells and cytotoxic T cells. Those cells secrete free radicals to destroy and phagocyte pathogens. TH2 secretes different cytokines (IL-4 and IL-10) that stimulate B cells to produce antibodies. Chronic stress suppresses TH1 but not TH2, thus causing suppression of cellular immunity but activation of humoral immunity. Excess humoral activity might lead to autoimmune disorders and allergy. As mentioned earlier, glucocorticoids that are involved in initiating this complex process serve also as the signal to stop it. With chronic social stress, it was demonstrated that leukocytes are less sensitive to glucocorticoid signaling to stop inflammation. The explanation for this is the glucocorticoid receptors (GRs) resistance model.

Glucocorticoid Receptors Resistance Model

Empirical Evidence

Several studies have demonstrated that the leukocytes of people exposed to chronic social stress have decreased sensitivity to the immunosuppressive effects of glucocorticoids. These studies used *in vitro* assays to compare the concentration of synthetic glucocorticoids needed to suppress the production of pro-inflammatory cytokines by leukocytes of subjects exposed to chronic social stress with controls. Some of the studies also assessed the steroid concentration needed to suppress leukocyte proliferation. Parents of children with cancer, exhausted industrial employees, and elderly caregivers of dementia patients were found to have increased resistance of leukocytes to the anti-inflammatory effects of glucocorticoids as compared to their respective control groups. Their leukocytes secreted high levels of pro-inflammatory cytokines despite incubation with high doses of glucocorticoids. Higher levels of glucocorticoids were needed to suppress leukocyte proliferation in stressed subjects as compared to unstressed subjects.

Pathophysiology

The mechanism that leads to glucocorticoid resistance in leukocytes is not fully understood. One explanation may be that chronic social stress leads to elevated levels of circulating glucocorticoids and to downregulation of leukocyte GR density. Another explanation, supported by several studies, is that

pro-inflammatory cytokines lead to decreased function of GRs. One pathway is by inhibiting GR translocation to the nucleus, and another one is induction of nonfunctioning isoforms of GR (GR-beta). Thus, a vicious cycle is created and a pro-inflammatory state is maintained even after the stress ends.

Clinical Implications

Stress is a fundamental part of human life. Chronic social stress is recognized as a common phenomenon with detrimental consequences. It has been linked to increased probability for infections, cancer, autoimmune disorders, allergy, cardiovascular disease, and drug abuse. Not everyone is vulnerable to the same degree to such challenge. Some of the differences are constitutional, like age, sex, or genetic make-up. Stress occurs when we perceive the demands that we are facing to be beyond our resources; thus, enhancing our resources may protect us. For example, social support was found to act as a buffer to increased GR sensitivity in parents of children with cancer. Improving our coping skills may help us handle stressful challenges. A promising direction of research on buffers to the detrimental outcomes of stress evolved from studies on major depression. Many patients suffering from major depression have been found to have dysregulation of the HPA axis, as do subjects confronting chronic social stress. This dysregulation is manifested through increased secretion of cortisol and decreased sensitivity of GR so that the net effect is probably too little glucocorticoid signaling. About half of the patients with major depression fail to suppress secretion of cortisol following an external dose of a synthetic steroid, namely, dexamethasone. This nonsuppression in dexamethasone suppression test (DST) is a predictor of poor prognosis, pointing to a high probability of relapse. The mechanism leading to nonsuppression in DST is probably related to decreased brain GR sensitivity. Nonsuppression in DST was correlated to elevated levels of pro-inflammatory cytokines, thus probably reflecting decreased sensitivity of GRs in leukocytes as well. High levels of pro-inflammatory cytokines such as IL-1 β , IL-6, and TNF- α were linked to increased risk of cardiovascular diseases, diabetes, osteoporosis, and brain cortical atrophy, observed in patients suffering from major depression. Treatment with antidepressants (AD) was reported to enhance glucocorticoid signaling by increasing GR number and function. The mechanisms involved in this response include induction of GR transcription as well as promoting translocation of GRs from the cytoplasm to the nucleus. Accumulating data indicate that the cyclic AMP (cAMP)/protein

Figure 1 Buffers to stress's detrimental outcomes.

kinase A (PKA) pathway is a key factor in the regulation of GR sensitivity. Phosphorylation of GR by PKA leads to higher sensitivity of the receptor, and hypoactivity of that pathway may be linked to GR resistance in major depression. Thus, ADs may enhance GR function by increasing phosphorylation of GR by the cAMP/PKA cascade.

Several studies involving glucocorticoid agonists as well as glucocorticoid antagonists were shown to have some efficacy for patients with major depression. These advancements in our understanding might lead the way to better prevention and treatment of people facing chronic social stress (Figure 1).

Anticancer Therapy and Genotoxic Stress

The Circadian Clock System: A Universal Timing
Mechanism

Circadian Clock System Modulates *in Vivo* Response to
Genotoxic Treatments

Glossary

Chronotherapy Timed delivery of therapeutic drugs at empirically established periods of higher efficacy and lower toxicity to the organism.

Circadian rhythms The 24-h periodicities in various biological processes (behavioral, physiological, and biochemical) that have evolved in response to the 24-h periodicity of the Earth's rotation. Controlled by an internal clock mechanism, these rhythms can persist in the absence of environmental cues (for example, in constant darkness), displaying oscillations with periodicities close to 24 h. They can also respond to external stimuli (light, in particular), which coordinate the phases of the internal clock and the light-dark cycle.

Genotoxic stress Condition induced in cells by exposure to different types of external and internal potentially harmful agents, which results in DNA damage and is recognized by the organism's stress response systems.

Molecular circadian oscillator Cell-autonomous oscillator that is formed by the products of core clock genes, which exhibit the 24-h periodicity in their expression/activity.

Peripheral oscillators Circadian oscillators that operate in peripheral (nonneural) tissues and generate rhythmic output in physiology.

Suprachiasmatic nucleus (SCN) The anatomical site of the mammalian circadian master clock. The SCN is composed of ~20 000 neurons residing in the anterior of the hypothalamus. The individual SCN neurons are capable of generating the 24-h periodicities in electrical and metabolic activity and are responsible for synchronization of peripheral circadian oscillators.

Anticancer Therapy and Genotoxic Stress

In the course of their lifetime, all cells, tissues, and entire organisms may be exposed to a variety of harmful agents that cause DNA damage (genotoxic stress). The endogenous sources of DNA-damaging agents result from normal cellular metabolism and include free radicals and peroxides. The most common sources of exogenous genotoxic agents are ultraviolet light, ionizing radiation, oxidative stress, and various chemical mutagens. DNA damage may also result from routine errors in DNA replication and recombination. To prevent detrimental effects on the genome, cells have evolved a response system that induces cell cycle arrest to allow sufficient time to repair the incurred damage, activates the appropriate DNA repair pathway, or, in the case of irreparable damage, induces apoptosis. Thus, response to genotoxic stress is a rather complex process that includes induction of multiple genes associated with cell cycle control, replication, DNA repair, apoptosis, signal transduction, etc. As a result, the cell's fate after genotoxic stress is determined by the superposition of multiple stress response pathways and depends on cell type, cell status, the level of damage, and environmental conditions.

Understanding the molecular mechanisms of cellular response to DNA-damaging agents as well as developing the tools for manipulating stress response have important medical applications, especially in the field of clinical oncology. Thus, two major types of existing anticancer treatments – chemotherapy and radiation – rely on induction of various types of damage to biological macromolecules in tumor cells. Because many of them specifically target DNA, these treatments induce genotoxic stress, which consequently induces the cellular stress response system. Though designed to selectively kill tumor cells, both chemotherapy and radiation are accompanied by nonspecific damage to normal cells and tissues, resulting in undesirable side effects.

One of the approaches that were developed to minimize these side effects was based on the observation that *in vivo* response to various therapies can display significant variation depending on the time of treatment. It has been suggested that these variations may result from differential daily response of both tumor and normal cells, and the final outcome reflects superposition of these effects. While the data on daily variations in therapeutic response of tumors are still

sporadic and sometimes inconsistent, daily variations in drug and radiation responses of normal tissues have been studied in more detail. Testing the effect of timed administration of more than 30 anticancer drugs in mice and rats clearly demonstrated that the drug's toxicity varied significantly throughout the day. In addition, several clinical studies indicate that chronomodulated drug administration results in a significant decrease in complications associated with certain types of cancer treatments while maintaining the same therapeutic effect. These variations in the organism's response to anticancer therapy may depend on different parameters: daily variations in the pharmacokinetics of a particular medicine, blood and tissue concentration of various growth factors, cytokines, and hormones, as well as daily variations in the activity of the intracellular genotoxic stress response system. The chronotherapeutic approach takes advantage of natural daily variability in the physiological response of an organism, which, along with many other parameters, is controlled by the circadian clock system.

The Circadian Clock System: A Universal Timing Mechanism

In mammals, various physiological parameters (such as the sleep–wake cycle, endocrine function, blood pressure, energy metabolism, and behavior) show a nearly 24-h rhythm that is controlled by an internal circadian clock system. This system is capable of generating periodicities even in the absence of environmental cues and at the same time responds to various external stimuli to synchronize the phases of the internal clocks with the environment.

The mammalian circadian clock is organized as a hierarchical network of numerous oscillators, with the master clock residing in the neurons of the hypothalamic suprachiasmatic nucleus (SCN). The master clock in the SCN synchronizes the phases of multiple peripheral clocks throughout the body with the natural 24-h light–dark cycle. Importantly, these peripheral clocks can respond to other synchronizing stimuli (for example, the liver's clock can be coordinated with the food intake schedule, thus functioning independently of the SCN). The ubiquitous nature of the clock mechanism and its ability to respond to a variety of external stimuli underscore the important role the circadian clock system plays in controlling different physiological parameters, including the response to genotoxic stress.

Insights on the mechanistic aspects of global circadian regulation were made possible by recent progress in understanding the functional organization of the molecular clock. It is now well established that, at

the molecular level, the mammalian circadian clock in all types of cells is formed by interdependent transcription/translation feedback loops (Figure 1). Two basic helix-loop-helix (bHLH) PAS-domain transcription factors, CLOCK and BMAL1, form the positive elements of the central oscillatory loop. The CLOCK/BMAL1 heterodimer binds to E box elements in the promoters of target genes and drives rhythmic transcription of three *Period* (*Per1*, *Per2*, and *Per3*) and two *Cryptochrome* (*Cry1* and *Cry2*) genes. When PER and CRY proteins are translated, they are translocated to the nucleus, where they act as potent inhibitors of CLOCK/BMAL1-mediated transcription. CLOCK/BMAL1 also controls transcription of *Rev-erb α* , which feeds back to periodically repress expression of *Bmal1*, thus regulating a positive limb of the feedback loop. Positive and negative elements of these regulatory loops function to coordinate transcriptional events at appropriate times to provide 24-h periodicities. In addition, several post-translational modifications (phosphorylation and sumoylation) play an important role in regulating clock proteins' stability, cellular localization, and functional activity.

The basal transcriptional nature of the core clock mechanism suggests that its control of the output signaling, which translates into daily variations in physiological and metabolic changes, is also transcription based. Indeed, large-scale transcriptional profiling studies have demonstrated that a large number of genes display 24-h periodicities in their mRNA abundance, suggesting that they function under direct (through the E box elements in their promoter regions) or indirect (through the intermediate targets)

Figure 1 Simplified schematic representation of the mammalian circadian autoregulatory feedback loop. Positive elements of the loop (CLOCK and BMAL1) dimerize to activate rhythmic transcription of *Per* and *Cry* genes through E box enhancer elements. The nuclear-localized CRY and PER proteins interact with CLOCK and BMAL1 to negatively regulate CLOCK/BMAL1-mediated transcription. *Rev-erb α* transcription is regulated by the same components that control *Per* and *Cry* transcription, and the resulting circadian accumulation of REV-ERB α leads to periodic repression of *Bmal1* transcription.

control of the circadian clock system. Interestingly, circadian transcriptional control demonstrates remarkable tissue specificity, suggesting that additional profiling of drug- and radiation-sensitive tissues may identify critical stress response genes that function under circadian control.

Circadian Clock System Modulates *in Vivo* Response to Genotoxic Treatments

The establishment of the functional link between the circadian and stress response systems was made possible by the availability of various circadian mutant mouse models. All circadian mutant mice display a common phenotype manifested by behavioral arrhythmicity and disrupted rhythmic gene expression. However, at the molecular level they represent two extreme states of circadian clock function in regard to CLOCK/BMAL1 transcriptional activity. The *Clock* mutant and *Bmal1*-deficient mice are characterized

by constant low levels of CLOCK/BMAL1 transcriptional activity, while mice with a deficiency of both CRYs contain CLOCK/BMAL1 in its maximally active state. The comparison of the sensitivity of these three types of mutant mice to the anticancer drug cyclophosphamide has shown a direct correlation of survival with the CLOCK/BMAL1 functional status. Thus, when compared to wild-type animals, mice with a deficiency in the positive components of the circadian transcriptional loop (CLOCK and BMAL1) are more sensitive to drug-induced genotoxic stress, while animals with a deficiency in negative elements (CRY1 and CRY2) are more resistant. At the same time, wild-type animals demonstrate daily variations in sensitivity to cyclophosphamide-induced genotoxic stress, which also correlates with normal daily variation in CLOCK/BMAL1 activity (Figure 2). The fact that these arrhythmic mutants display opposite phenotypes suggests that sensitivity to genotoxic stress does not depend on persistence of

Figure 2 Animals' *in vivo* sensitivity to genotoxic stress correlates with the functional activity of CLOCK/BMAL1 transcriptional complex. (a) Body weight loss of the wild-type and circadian mutant mice after cyclophosphamide treatment. Wild-type animals injected at 3 a.m. demonstrate greater sensitivity to the drug-induced toxicity compared to their littermates injected at 3 p.m. *Clock/Clock* and *Bmal1*^{-/-} animals demonstrate greater sensitivity to cyclophosphamide at all times tested. *Cry1*^{-/-}*Cry2*^{-/-} mice are more resistant to the treatment. (b) Schematic representation of the correlation between daily or locus-specific variations in CLOCK/BMAL1 functional activity (black line) and resistance to the treatment (red bars) in animals of various circadian genotypes.

rhythmicity per se, but rather is guided by the activity of the major circadian transactivation complex.

Mutants with a deficiency of the PERIOD protein represent another example of the functional link between the circadian and genotoxic stress response systems. These mice display higher sensitivity *in vivo* to long-term effects of low doses of ionizing radiation, while the primary thymocytes from these animals are more resistant to high doses of radiation in short-term experiments. Taken together, these data suggest that circadian variations in an organism's sensitivity to various types of genotoxic treatments are determined by the rhythms in expression and activity of the core circadian proteins.

How can rhythms in the activity of circadian proteins modulate response to genotoxic stress? It is well known that different types of cellular stress lead to induction of multiple transcription factors (i.e., p53, NF- κ B or AP1 induction by radiation, induction of NF- κ B during the immune response, or HIF1 α in response to hypoxia). They in turn activate downstream transcriptional targets, encoding factors important for cell death or survival. The balance of these factors will determine the cellular and organism response to genotoxic treatments. Since the circadian clock controls the output at the transcriptional level, some of the responsive genes may be direct targets of CLOCK/BMAL1. Although not yet confirmed, this view is supported by the fact that the CLOCK/BMAL1 complex directly controls such important regulators of transcription as DBP, REV-ERB α , and ROR α . In addition, the CLOCK/BMAL1 complex may display dual transcriptional activity, acting both as transcriptional activator and transcriptional repressor, depending on its interaction with CRYs. Importantly, while functioning as a repressor, it could interfere with the ability of other transcription factors to activate the same promoter. Thus, those genes that are controlled by both the circadian and stress response systems will be induced in response to genotoxic treatments only at those times of day when CLOCK/BMAL1 is functioning as an activator and

will be attenuated at the times when it functions as a repressor. As a result, the balance between pro-death and pro-survival pathways will vary depending on the status of the circadian transcriptional complex. Importantly, these recent findings identify CLOCK/BMAL1 as a potential target for a rational search for pharmacological modulators of the organism's response to genotoxic stress that may potentially be used in clinical practice to minimize the side effects of cancer treatment.

Glossary

<i>Aortic aneurysm</i>	Dilatation or ballooning of the wall of thoracic or abdominal aorta.
<i>Chronobiology</i>	The study of biological systems as affected by time.
<i>Circadian rhythm</i>	Biological rhythm with regular recurrence in cycles of about 24 h.
<i>Coagulation</i>	Process of interaction of blood coagulation factors to form a fibrin clot.
<i>Hypertension</i>	Persistently high systemic arterial blood pressure.
<i>Myocardial infarction</i>	Necrosis of the myocardium, as a result of interruption of blood supply.
<i>Stroke</i>	Sudden and severe cerebral attack, ischemic or hemorrhagic.

Chronobiology and Circadian Rhythms

Chronobiology is a branch of biomedical sciences devoted to the study of biological rhythms. Biological rhythms exist at any level of living organisms and, according to their cycle length, may be divided into three main types: (1) circadian rhythms (from the Latin *circa diem*, characterized by a period of approximately 24 h), (2) ultradian rhythms (period shorter than 24 h, e.g., hours, minutes or even seconds), and (3) infradian rhythms (period longer than 24 h, e.g., days, weeks, months). Circadian rhythms are the most commonly and widely studied biological rhythms.

The cardiovascular system is organized according to a specific temporal order that is oscillatory in nature, and most cardiovascular functions exhibit circadian changes. Such predictable-in-time differences in the physiological status of the cardiovascular system

give rise to rhythmic variations in the susceptibility of human beings to morbid and mortal events. On the other hand, the pathological mechanisms of cardiovascular disease themselves exhibit temporal changes in both their manifestation and severity, leading to predictable-in-time differences in their ability to precipitate and graduate the overt expression of disease. A growing body of evidence suggests that the occurrence of cardiovascular events is not evenly distributed in time, but shows peculiar temporal patterns that vary with time of the day, the day of the week, and the month of the year. These patterns coincide with the temporal variation in the pathophysiological mechanisms that trigger cardiovascular events and the physiological changes in the body rhythms. These contribute to the definition of the new concept of chronorisk, in which several factors, not harmful if taken alone, are capable of triggering unfavorable events when presenting all together within the same temporal window.

Circadian Rhythm of Cardiovascular Events

Myocardial Ischemia and Infarction

Coronary heart disease (CHD) is the number one cause of death worldwide, leading to more than 7 million deaths annually. CHD occurs when the coronary arteries are unable to supply adequate oxygenated blood to myocardial tissue, leading to myocardial ischemia and possible acute myocardial infarction (AMI). A reversible injury to myocardial tissue leads to ischemia, while AMI represents cell death after prolonged ischemia. The development of AMI is based on two major components. The first is vascular injury and/or dysfunction with loss of a non-thrombogenic endothelial surface, most frequently due to atherosclerotic plaques. In response to intraluminal stress, for example, the circadian periodic or incidental rise in blood pressure, plaques may rupture and release thrombogenic factors into the bloodstream. The second is activation of the blood-clotting mechanism beyond the capacity of the simultaneously activated fibrinolytic mechanisms to remove the fibrin formed and prevent the formation of a clot, thus leading to occlusion of the vessel.

As for circadian variation in onset, both stable coronary disease and ischemic attacks with ST segment

elevation show a peak in the morning hours, particularly in the first few hours after waking and commencing activity. Myocardial infarction shows an evident circadian rhythm as well, characterized by a higher frequency of onset during morning hours. It has been estimated that the incidence rate of AMI onset is 40% higher in the morning period than throughout the rest of the day, and nearly 28% of morning infarctions and 22% of sudden cardiac deaths (accounting for approximately 9% and 7% of all AMIs and sudden deaths, respectively) are attributable to the morning excess. Compared with all other times of the day, morning shows a relative risk of AMI of 1.4, rising to a threefold increase in the first 3 h after waking, when almost 25% of all AMIs occur. A series of studies has indicated that this circadian pattern in the incidence of AMI was similar in different subgroups of patients and was independent of gender, age, and clinical characteristics, for example, lower or higher ejection fraction, presence of one-, two-, or three-vessel disease, type of infarction (Q-wave or non-Q-wave), and site of infarction (anterior or inferior). Diabetes mellitus, however, represents a peculiar entity. Diabetic subjects, who are more at risk of AMI compared with nondiabetics, show attenuation of morning peak or, in some cases, the absence of a significant circadian variation of AMI onset. It is thus possible that diabetic subjects are exposed to a steady and high risk of myocardial infarction during the 24 h, maybe due to a marked diminution of parasympathetic activation during sleep.

Drugs may also suppress diurnal variation. Specifically, an absence or attenuation of the morning peak of AMI has been observed in patients taking β -blockers. Additionally, in those taking aspirin, the primary morning peak of infarction was attenuated: there was an additional 25% protective effect associated with aspirin specifically between 4 and 10 a.m., the hours of awakening from sleep and assuming the upright posture.

Stroke

Stroke is the end result of a heterogeneous group of vascular diseases that are manifested by ischemia or hemorrhage of one or more vessels of the brain. Worldwide, stroke is the second leading cause of death and the leading cause of disability and long-term care costs. Although the frequency of and mortality from stroke have declined in the United States and many other industrialized countries during the past 30 years, in the United States stroke continues to affect ~700 000 persons and to cause ~165 000

deaths per year, and a similar or even higher incidence of stroke is reported in other countries. A number of studies have indicated that the incidence of all subtypes of stroke (e.g., lacunar, thrombotic, embolic, and hemorrhagic) shows a significant circadian rhythm, characterized by a higher frequency during morning hours. A comprehensive meta-analysis of 31 separate studies in which the clock time of events was verifiable confirmed the prominent 24-h pattern of cerebrovascular events. Thus, for example, the incidence of transient ischemic attack (TIA) and hemorrhagic and ischemic stroke reaches a peak between 6 and 12 a.m. Approximately 55% of all ischemic strokes, 34% of all hemorrhagic strokes, and 50% of all TIAs occurred during this temporal window.

Rupture/Dissection of Aortic Aneurysm

Acute aortic dissection and rupture of aortic aneurysms are serious, life-threatening cardiovascular emergencies that carry high fatality rates. In fact, many patients with either an acute aortic dissection or rupture of an aortic aneurysm die before hospitalization, and data from the large population enrolled in the International Registry of Acute Aortic Dissection (IRAD) show a 24% mortality rate in patients reaching hospitals even in centers with advanced technology and considerable expertise. Also, several studies have found a circadian variation for aortic aneurysm, characterized by an increased risk of both aortic rupture as well as aortic dissection during early hours of morning. Analysis of the IRAD registry showed that this morning peak (around 8–9 a.m.) was independent of gender, type A or B dissection, age $<$ or $\geq$ 70 years, and presence or absence of hypertension.

Circadian Rhythm of Underlying Risk and Triggering Factors

Several variables indicative of cardiovascular and cerebrovascular status exhibit prominent circadian rhythms and may contribute to the circadian pattern of cardiovascular events ([Figure 1](#)).

Vascular Tone and Arterial Blood Pressure

Sympathetic activity is circadian rhythmic, reaching peak level in the morning when vascular receptors exhibit greatest sensitivity, and this can play a role in the sharp morning rise in arterial blood pressure (BP) and heart rate (HR). The morning rise in BP is significantly amplified by biological responses to events that occur upon awakening from nighttime sleep, that is, assumption of upright posture, commencement of physical activity, and exposure to

Figure 1 Schematic outline of the way in which several concurring risk factors might contribute to trigger the onset of acute myocardial infarction during morning hours. Abbreviations: REM, rapid eye movement; 5HT, 5-hydroxytryptamine; PTT, partial thromboplastin time; APTT, activated partial thromboplastin time; PAI-1, plasminogen activator inhibitor-1; t-PA, tissue plasminogen activator.

emotional stress, all of which further elevate catecholamine secretion and sympathetic tone. The circadian variation in BP, characterized by a double peak in the early morning and in the early evening, plays an important role in the onset of cardiovascular and cerebrovascular events. Moreover, night BP levels are important as well. In normotension and in uncomplicated essential hypertension, in fact, systolic BP (SBP) and diastolic BP (DBP) normally decline during nocturnal sleep by 10–20% relative to the respective daytime mean levels. Some persons exhibit a so-called nondipping pattern, that is, a less than 10% decline (or even rise) in SBP and/or DBP during nighttime sleep relative to their daytime levels. The cumulative effect over time of abnormally elevated nighttime BP load on target organs, for example,

heart, brain, and kidney, may lead to deleterious effects.

Blood Coagulation and Fibrinolysis

Circadian rhythms in blood coagulation and fibrinolysis are also key components of the multifactor pathogenesis of cardiovascular and cerebrovascular events and their 24-h patterns. The *in vitro* aggregation response of platelets to stimulants such as ADP and epinephrine is circadian rhythmic, and each of these rhythms peaks during the late night or morning hours and declines to the trough in the afternoon. Activation of platelet aggregation is brought about by the increased secretion of catecholamines, which is initiated by the activation of the sympathetic nervous

system during nocturnal episodes of rapid eye movement (REM) sleep. Since REM episodes are more frequent during final hours of nighttime rest in normal sleepers, the rise in catecholamine concentration commences at that time, and increases further in the morning due to baroreflex with the change from supine to upright posture upon awakening and the commencement of physical activity and exposure to emotional stress. Moreover, circadian rhythms have been found in several factors of the coagulation cascade, on the intrinsic as well as the extrinsic and common pathways of blood coagulation. Circadian rhythms in factors II (thrombin), VII (tissue thromboplastin), VIII, and IX, with peak activity in the morning hours, were observed in clinically healthy human subjects.

As a result of these rhythms, the global screening tests of different steps in the coagulation cascade, such as prothrombin time (PT) and activated partial thromboplastin time (aPTT), show the lowest values (indicative of blood hypercoagulability) in the morning. The extent of the differences in PT, aPTT, and thrombin time (TT) was found to be about 10% of the respective means.

Activation of the coagulation cascade is followed in healthy subjects by an increase in fibrinolytic activity, which serves to limit the coagulation process and avoid vascular occlusion. Fibrinolysis also shows an evident circadian rhythmic variation. The circadian rhythm in fibrinolysis, although dependent on multiple influences, is to a large extent determined by the interaction between tissue plasminogen activator (t-PA) and its potent inhibitor, tissue plasminogen activator inhibitor-1 (PAI-1). Both t-PA antigen and PAI-1 antigen are circadian rhythmic, showing peak concentrations in the morning, but the circadian rhythm of t-PA activity is almost 12 h out of phase with the circadian rhythm in t-PA antigen concentration. Thus, PAI-1, the activity of which parallels its concentration, suppresses t-PA activity during the late night and early morning hours when thromboembolic events are most frequent. The circadian rhythm in PAI-1 is of large amplitude, showing excursions as great as 250%, thereby contributing in diurnally active subjects to the relative hypercoagulability of the blood in the morning and relative hypocoagulability of the blood in the evening.

Stress and Circadian Rhythms

At least two major physiological systems play a crucial role in the adaptation of the organism to environmental challenges: the circadian system and the stress response system, which are tightly coupled.

Activation of the hypothalamic-pituitary-adrenocortical (HPA) axis in response to stressful stimuli is

a crucial mechanism that allows an organism to maintain homeostasis and adapt to environmental conditions. It is known that HPA has a circadian activity in basal activity, and the rhythmicity in secretory activity is controlled by the suprachiasmatic nucleus (SCN) of the hypothalamus. However, the SCN is not the only biological clock. In fact, cloning of the clock genes in the late 1990s revealed that clock genes are expressed and oscillate with a circadian rhythm in each organ or cell, suggesting that each of them has its own internal clock. Thus, this clock system has been denominated as a peripheral clock in comparison with the central clock in SCN. It seems that the SCN-based central clock is capable of synchronizing peripheral clock systems.

Stress-induced secretion of corticotropin-releasing factor (CRF) from the paraventricular nucleus (PVN) of the hypothalamus triggers the synthesis and release of ACTH and, ultimately, glucocorticoids. Thus, the hypothalamic PVN receives convergent information from both stress and the circadian clock, and it has been demonstrated that, at least in mice, the mammalian orthologs *Per1*, *Per2*, and *Per3* of the *Drosophila melanogaster* clock gene *Period* are expressed in different areas of the central nervous system (e.g., PVN) and peripheral tissue.

Stress is capable of exerting major effects upon the circulatory system of coronary patients, particularly in the morning. Stress acts on the cardiovascular system in multiple ways, and a direct link has been demonstrated in both laboratory and ambulatory studies between emotional stress and changes in HR, systolic and diastolic BP, left ventricular stroke work, cardiac output, blood viscosity, and coagulation. These and other stress-related changes can trigger angina in coronary syndrome patients and are perceived to act in a primary or secondary way in the triggering cerebrovascular events through the sudden increase in BP and blood coagulation. Acute coronary syndromes may also be triggered by emotional stress, and studies demonstrated that emotional stress preceded the onset of AMI in 11% of men and 16% of women. Anger is important as well, and it has been reported that there is a twofold increased relative risk of acute coronary syndromes in the 2 h after an emotional burst of anger. Mental stress has also been shown to inhibit flow-mediated brachial artery vasodilatation, a validated indicator of endothelial function, and the hemodynamic response to mental stimuli, consisting of the combination of a reduction in blood supply and an increase in cardiac demand, might explain the role of mental stress in the onset of myocardial ischemia. Indeed, the effect of stress on human cardiac, vascular, and hemostatic status appears to be circadian rhythmic, with the effects

being greater in the morning. Experimental studies on rats showed the molecular mechanisms of stress-induced heart attacks, with a rapid activation of the p44/p42 mitogen-activated protein kinase, followed by transient upregulation of the immediate early genes of the smooth muscle cells of the coronary arteries, endothelial cells, and myocardium. It is interesting to observe that the 24-h pattern of acute cardiovascular and cerebrovascular events is tightly coupled in time, suggesting that they share numerous risk factors. An exaggerated cardiovascular response to behavioral challenges has been suggested as a potential factor that enhances the risk of hypertension and CHD. Thus, individuals who exhibit large increases in BP during acute psychological stress are at risk for atherosclerosis, probably secondary to endothelial damage by BP surge, via increased flow turbulence and subsequent release of inflammatory and pro-atherogenic cytokines.

Emotional stress can also play a role in the triggering of stroke. In patients with acute ischemic stroke, the finding that salivary cortisol levels are positively correlated with 24-h and nighttime BP suggests that stress may induce endocrine changes that result in BP increase. In asymptomatic older adults, stress-induced BP reactivity is enhanced in those diagnosed with silent cerebrovascular disease, independently of the resting BP levels, suggesting that mental stress at the start of the day can intensify the morning BP surge and contribute to the higher frequency of strokes at this time.

Circadian Rhythms and Possible Implications for Treatment of Cardiovascular Diseases

In conclusion, it seems that the temporal rhythmic organization of the vascular functions is such that the defense mechanisms against disease are incapable of providing the same degree of protection at all times of the day. A point of interest is the possible influence on chronobiologic rhythms and outcome of cardiovascular events. At present, only a limited amount of data is available on the prognostic implications of the concept of chronorisk. For example, the clock time of onset seems to affect the clinical course and outcome of patients with AMI. Moreover, the concept of chronorisk implies that the delivery of protective or preventive medications should be synchronized in time in proportion to need as determined by established rhythmic patterns in cardiovascular risk, during the 24 h and in a manner that will avert or minimize undesired side effects. A chronotherapeutic approach to cardiovascular diseases has been suggested. For example, a growing interest is given to

morning BP surge as an important risk factor. It is known that some drugs have different effects when administered in the morning compared to in the evening. In fact, it should not be assumed that a long-acting, once-daily antihypertensive drug administered in the morning will have the same antihypertensive effect as when administered in the evening. Thus, the effects of time of drug administration on the pharmacodynamics of antihypertensive drugs are an important consideration for antihypertensive therapeutics. Improved control of the morning BP surge by means of a tailored antihypertensive therapy might provide maximal benefit during the particularly vulnerable time periods.

Prenatal Stress, an Early Environmental Change during
a Critical Period

Circadian Rhythms and Adaptation to External
Environment

Influence of Prenatal Stress on Circadian Rhythmicity,
Sleep, and Behavior

Conclusion

Glossary

Circadian rhythms Biochemical, physiological and behavioral processes occurring in a cyclic fashion with a period of about 24 h (*circa die* = about a day).

Free-running Term used to characterize the expression of circadian rhythms in the absence of any 24 hr synchronizing information from the external environment.

Sleep-wake cycle The various vigilance states were characterized as follows. Wake (W): low voltage fast electroencephalogram (EEG) activity, high electromyogram (EMG) activity and numerous eye movements; Light slow wave sleep (SWS1): high voltage slow cortical waves interrupted by low voltage fast waves and reduced EMG activity; Deep slow wave sleep (SWS2): continuous high

amplitude slow wave activity in EEG, very low EMG activity and no electrooculogram (EOG) activity; Paradoxical sleep (PS): low voltage fast cortical waves with a regular theta rhythm, absence of muscular tone and presence of rapid eye movements.

Phase shift

A discrete displacement (advance or delay) of an oscillation (e.g. circadian activity rhythm) along the time axis, in response to a synchronizing stimulus.

Prenatal stress procedure by restraining pregnant females

Pregnant females were individually restrained three times a day (at 09:00, 12:00 and 17:00 h) for 45 min in transparent plastic cylinders (7 cm diameter, 19 cm long) and exposed to bright light. This manipulation was performed daily during the last week of pregnancy until delivery. Control pregnant females were left undisturbed in their home cages.

Prenatal stress procedure by gestational hypoxia

Pregnant females were exposed to hypoxia from the 5th to 20th day of gestation, by housing them in Plexiglas chambers with a normobaric hypoxic atmosphere consisting of 10% O₂ – 90% N₂. Control pregnant females were kept in normoxia (21% O₂).

Prenatal Stress, an Early Environmental Change during a Critical Period

The prenatal environment exerts a profound influence on the development of an organism, inducing changes that extend from early to later life. In animal models of prenatal stress (PNS), it has been shown that adult prenatally stressed rats exhibit abnormalities under stressful conditions, such as increased anxiety-like behaviors, hyperemotionality-like behaviors, or depression-like behaviors. Among the biological

substrates possibly mediating these behavioral disorders, the hypothalamic-pituitary-adrenal (HPA) axis, involved in an animal's ability to cope with stress, appears to be a good candidate. Indeed, PNS induces an increase in stress-induced plasma adrenocorticotrophic hormone (ACTH) levels, a prolongation of stress-induced corticosterone secretion, and a decreased binding capacity of hippocampal corticosteroid receptors. These behavioral and physiological changes seem to depend on the gender of the animals, with substantially more marked effects of PNS in females than in males. Among the neurotransmitters involved in those hormonal and behavioral responses, acetylcholine plays a critical role. Indeed, PNS has long-term effects on the development of forebrain cholinergic systems and induces an increase in hippocampal acetylcholine release after acute stress or corticotropin releasing hormone (CRH) microinjections. Those long-term neuroendocrinological effects are mediated, at least in part, by a stress-induced maternal corticosterone increase during pregnancy.

Taken together, these studies support the idea that PNS disrupts the organism's capabilities to cope with stress and that prenatally stressed rats have biological traits similar to those observed in depressed patients. Indeed, like depressed patients, prenatally stressed rats do escape from the feedback inhibition responsible for returning corticosterone secretion to basal levels after stress. Finally, like depressed patients, in whom cholinergic hyperactivity is described, prenatally stressed rats exhibit cholinergic hypersensitivity after a CRH challenge.

Circadian Rhythms and Adaptation to External Environment

Most biochemical, physiological, or behavioral processes within the organism fluctuate on a regular basis throughout the 24-h day. These daily rhythms arise from an internal time-keeping system, the circadian clock, located in the hypothalamic suprachiasmatic nuclei (SCN). In the absence of any environmental input, these rhythms persist with a period of approximately 24 h and are therefore referred to as circadian rhythms.

The circadian time-keeping system is essential for the optimal functioning and adaptation of the organism to the dramatic changes in the environment imposed by Earth's rotation on its axis. Indeed, the circadian system maintains temporal synchronization not only between the organism and daily changes in the physical environment but also between diverse internal physiological processes. For many years, the circadian system was thought to be sensitive only to changes in the light-dark (LD) cycle. However, it

has been shown that circadian function and/or sleep patterns can also be reset by neurochemical or behavioral stimuli. Among those stimuli, steroids can have marked effects on the functioning of the circadian system, and chronic stress in adult rats can induce changes in sleep patterns and circadian rhythms.

Perinatal events seem to have complex influences on the long-term development of circadian function. For instance, it is known that the abnormal development of visual system in anophthalmic mice has clear effects on the integrity of the SCN and on the development of behavioral rhythms. Restricted access to their natural mother has been shown to shift the endogenous corticosterone rhythm of rat pups. Despite the fact that postnatal events have complex influences on the long-term development of the circadian clock, very little attention has been given to the possible effects of prenatal stress on circadian clock function. Previous studies reported that sustained hypoxia in adults affects the functioning of the internal clock located in the SCN. We hypothesize that gestational hypoxia, found in many pathological conditions in pregnant women and naturally associated with life at high altitude, can cause long-lasting consequences for the synchronization of the circadian clock to light.

Influence of Prenatal Stress on Circadian Rhythmicity, Sleep, and Behavior

We recently showed a phase advance in the timing of the rise of corticosterone in prenatally stressed rats compared to control rats. More precisely, PNS induced higher levels of total and free corticosterone secretion at the end of the light period in both males and females and induced hypercorticism over the entire diurnal cycle in females. The effects of prenatal stress on corticosterone secretion could be mediated, at least in part, by a reduction in hippocampal corticosteroid receptors at specific times of day. Results also show that prepartal stress can alter the pattern of corticosterone secretion in pregnant females. We also showed significant phase advances in the circadian rhythm of locomotor activity relative to the entraining LD cycle in prenatally stressed rats. When subjected to an abrupt shift in the LD cycle, male and female prenatally stressed rats resynchronized their activity rhythm to the new LD cycle slower than control rats. In temporal isolation in constant darkness, the free-running period of locomotor activity was significantly shorter in prenatally stressed rats compared to control rats.

In view of those changes in circadian rhythmicity, we investigated the effects of PNS on the sleep-wake cycle in adult rats. Male prenatally stressed rats

exhibited a significant increase in the amount of paradoxical sleep (PS) over the 24-h recording session, positively correlated to plasma corticosterone levels. Other changes include an increased sleep fragmentation and light slow wave sleep (SWS1) time and a slight decrease in the percentage of deep slow wave sleep (SWS2) relative to total sleep time. The present results demonstrate that exposure to PNS can produce long-term and selective changes in both the structure and continuity of sleep. Although there were preliminary reports of abnormal sleep-like behaviors in prenatally stressed monkeys and prenatally stressed humans, our data provide the first polygraphic demonstration of the long-term effects of PNS on the sleep–wake cycle when the animals reach adulthood.

Using gestational hypoxia as an alternative prenatal stress procedure, we demonstrated that, once they become adults, rats born to hypoxic mothers had significant alterations in their circadian rhythm of locomotor activity (recorded in freely accessible running wheels). Under a regular LD cycle, they showed a phase advance of their rhythm of activity and were less active than control rats. After an abrupt 6-h phase delay in the LD cycle, rats from the prenatal hypoxic group (PNH) took significantly more time to resynchronize to the new LD cycle than the controls. Under constant darkness, PNH and control rats had a similar period of activity, but the response of PNH rats to a light pulse in the early subjective night was less marked than of control rats. When submitted to acute restraint stress, PNH rats had a prolonged secretion of corticosterone compared to controls. These results indicate that prenatal hypoxia is a factor that has long-lasting consequences for the functional output of the biological clock and the hormonal response to stress.

Conclusion

Taken together, our results indicate that PNS or PNH induces an increased stress response and abnormal circadian and sleep functions in adult rats, suggesting an underlying dysfunction of the circadian clock. Our results parallel, to some extent, circadian and sleep changes found in depressed patients. Indeed, abnormalities in a variety of overt circadian rhythms, including the cortisol rhythm, have been documented in depressed patients. Also, alteration in the sleep–wake cycle is a hallmark of human depression, with changes including a shortened PS latency, an increase in the amount and frequency of PS during the first part of the night, increased sleep fragmentation, and a decrease in the amount of slow wave sleep.

Added to our previous findings of higher anxiety-like behaviors and hyperemotionality-like behaviors

in prenatally stressed rats, the dysfunction of their HPA axis and circadian timing system and the observation of long-term changes in their sleep structure support the validity of PNS models as a possible animal model of depression. In contrast to other stress-related animal models of depression, the persistence of all induced abnormalities after stressor removal in PNS or PNH rats can be seen as particularly advantageous for the design and testing of new therapeutic strategies in mood and sleep disorders.

The Molecular Circadian Clock

The Molecular Clock Is Not Confined to the SCN

Disruption of Molecular Clock Leads to Tissue and Organismal Dysfunction

Glossary

<i>Circadian clock</i>	An internal timing mechanism that regulates the expression of circadian rhythms. In mammals, a master circadian clock is located in the hypothalamic suprachiasmatic nucleus (SCN), although recent findings indicate that most if not all tissues of the body contain circadian clocks that are directly or indirectly regulated by the clock in the SCN.
<i>Circadian clock genes and clock-controlled genes</i>	While only a small number of genes and their protein products appear to be involved in the transcriptional/translational feedback loop that makes up the molecular core of the circadian clock, this molecular clock in turn appears to regulate the expression of hundreds of downstream clock-controlled genes.
<i>Circadian rhythms</i>	Biochemical, physiological, and behavioral events that reoccur in a cyclic fashion with a period of about 24 h.
<i>Entrainment</i>	Process by which an internal circadian clock is entrained or synchronized to the period of an external stimulus that

usually has a period of about 24 h. In nature, the light–dark cycle is the primary external environmental signal that entrains the circadian clock to the 24-h period of the day that is due to the rotation of the earth on its axis.

Free-running

Term used to describe circadian rhythms persisting in the absence of any 24-h synchronizing information from the external environment. The expression of free-running circadian rhythms with a period close to (e.g., 23–24 h) but rarely exactly 24 h demonstrates the endogenous nature of the circadian clock underlying the expression of circadian rhythms.

Period

The length of a cycle of the rhythm. The period of a free-running rhythm is considered a fundamental property of the circadian clock.

Phase

The timing of the rhythm. During entrainment, the timing of a phase reference point (such as activity onset) relative to the external time cue (such as lights on) should be stable. This relative timing is referred to as the phase angle of entrainment. The rhythm-resetting response to a perturbation such as a brief light exposure is measured as a phase shift.

The Molecular Circadian Clock

Early studies in invertebrates demonstrated that the period of the circadian clock was clearly under genetic control since 24-h rhythms developed in organisms never experiencing any 24-h changes in the physical environment. Furthermore, rearing mice on non-24-h cycles as extreme as 20 or 28 h has only small (i.e., on the order of a few minutes) and transient effects on

the free-running period of the circadian clock when animals are subsequently housed under conditions of constant darkness (i.e., the free-running period remains within a few minutes of 24 h). Until recently, evidence that genetic differences define the characteristics of the circadian clock system in mammals has been determined primarily by comparing properties of circadian rhythms between different inbred strains of the same species.

With the discovery of the first mammalian circadian clock gene (named *Clock*) in 1997, a new era opened for discovering how the mammalian circadian clock ticks. The *Clock* gene was initially identified through a behavioral phenotypic screen of mice that were the offspring of mutagenized animals. Vitaterna et al. identified a mutant animal that demonstrated a lengthened circadian period under free-running conditions (constant darkness). Descendants of this mutant with two copies of the mutant gene initially showed a free-running period of about 27–28 h in constant darkness, with subsequent breakdown in circadian rhythmicity. Next, the *Clock* gene was cloned and found to encode a member of the bHLH-PAS (basic helix-loop-helix, Per-Arnt-Sim domain) family of transcription factors. The role of the putative *Clock* gene was confirmed by creating transgenic mice in which the altered phenotype of *Clock* mutants was rescued by insertion of the wild-type *Clock* gene.

Other key clock genes in mammals have since been characterized. Three murine homologs of the *Drosophila period* gene, *mPer1*, *mPer2*, and *mPer3* have been identified. While double-knockout animals lacking *mPer1* and *mPer2* show behavioral arrhythmicity when placed in constant conditions, there appears to be partial redundancy of function between *mPer* family members. Moreover, *mPer3* does not appear to have an essential function in the core clock mechanism.

A second bHLH-PAS transcription factor, BMAL1, has been identified and shown to be a core circadian clock gene. *In vitro*, CLOCK-BMAL1 dimers activate transcription of *mPer*, and the *Clock* mutation described previously is associated with reduced expression of *mPer1*, *mPer2*, and *mPer3* in the suprachiasmatic nucleus (SCN). These data support a role for CLOCK (and the CLOCK-BMAL1 dimer) in activation of transcription of all three *mPer* homologs.

Two cryptochrome genes, *Cry1* and *Cry2*, also appear to be components of the core circadian system. *Cry2* null mutants exhibit lengthened circadian periods, while *Cry1* null mutants exhibit shortened circadian periods. In *Cry* double-knockout mice, animals are completely arrhythmic immediately after the introduction of constant darkness. CRY1 and CRY2

are both synthesized in the SCN, where at least *Cry1* exhibits rhythmic expression. These proteins inhibit CLOCK-BMAL1-driven transcription, most probably due to binding of CRY1 and CRY2 to clock components. Importantly, CRY1 and CRY2 are able to translocate *per* gene products to the nucleus.

Posttranslational modification of clock proteins seems to be important in the modulation of circadian rhythm. Casein kinase I ϵ (CKI ϵ), which phosphorylates CRY1, CRY2, PER1, PER2, and BMAL1, is defective in the *tau* mutant in Syrian hamsters, in which the free-running period in constant darkness is 22 h and 20 h in heterozygous and homozygous animals, respectively. In this mutant, CKI ϵ has a lower rate of phosphorylation. Recent data also suggest that a second kinase, CKI δ , is important for the mammalian clock.

The current concept of the core clock is a system of interacting transcriptional/translational feedback loops (Figure 1). The two transcription factors, CLOCK and BMAL1, form dimers that bind to DNA and promote rhythmic transcription of three *Per* genes, two *Cry* genes, and the *Rev-Erb α* gene (step 1). The proteins encoded by *mPer1* and *mPer2* bind to the proteins encoded by *Cry1* and *Cry2*, forming complexes with casein kinases (step 2). These translocate into the nucleus, where CRY and PER proteins act as negative regulators, directly inhibiting CLOCK/BMAL1 activity and indirectly the transcription of *mPers*, *Crys*, and *Rev-Erb α* (step 3). Positive feedback is mediated by rhythmic modulation of *Bmal1* transcription. Thus, the REV-ERB α protein, whose synthesis is increased by binding of CLOCK/BMAL1 dimers to DNA, inhibits the transcription of *Bmal1* (step 4).

Recent studies indicating that other genes involved in the posttranslational modification of circadian clock proteins can alter the circadian clock suggest that many other genes may be found that can modify the core genes/protein products of the molecular clock and alter its periodicity.

The Molecular Clock Is Not Confined to the SCN

With the establishment of the bilaterally paired SCN of the hypothalamus as the site of the circadian clock in mammals, considerable attention was focused on how the SCN can generate circadian rhythms at the neural as well as molecular levels. However, once the core components of the molecular circadian clock were identified, a surprising discovery was made: the clock genes not only are expressed in the SCN, but also are rhythmically expressed in the SCN and peripheral tissues throughout the body, including the

Figure 1 See text for explanation of figure.

Figure 2 See text for explanation of figure.

liver, heart, lungs, and muscle. Furthermore, these circadian oscillations in the peripheral tissues can persist for many cycles *in vitro*, revealing the endogenous nature of tissue-specific circadian rhythmicity. Most importantly, not only are the clock genes oscillating

in various tissues, but also they appear to be regulating the transcription of hundreds of downstream clock-controlled genes. In a simplistic form, our understanding of the circadian clock system is as follows (Figure 2):

1. The circadian clock genes and their protein products compose a transcriptional/translational molecular feedback loop (with posttranslational components) that can generate precise circadian timing in the master circadian clock in the SCN.

2. The SCN communicates circadian information to other central and peripheral tissues via neural and/or neurohormonal transmission vectors.

3. Non-SCN circadian clocks appear to consist of a molecular core, as does the SCN. Thus, the molecular clock in the SCN (which is itself entrained by the light–dark cycle) somehow entrains a similar molecular clock in other CNS and peripheral tissues. This entrainment may be direct or indirect via the SCN control of metabolic and behavioral rhythms (e.g., feeding, sleep–wake cycle, body temperature).

This simple three-step process does not rule out the possibility that downstream (from SCN) circadian oscillators will not persist on their own (e.g., in SCN-lesioned animals). Nor does it exclude the possibility that they can be entrained by environmental factors (e.g., when feeding occurs out of phase with the normal SCN-timed control of feeding). However, under normal entrained conditions, it appears that the SCN serves as the conductor of an orchestra in regulating the timing, directly or indirectly, of hundreds of downstream oscillators, which in turn are regulating the timing and expression of hundreds, if not thousands, of clock-controlled genes. Such intricate and diverse timing raises profound questions about the role of such timing in health and disease at many levels of organization.

Disruption of Molecular Clock Leads to Tissue and Organismal Dysfunction

A foundation of the field of biological rhythms is that the circadian clock system has evolved to allow organisms to maintain two different kinds of synchronization. One type of synchronization, referred to as external synchronization, enables the organisms to maintain synchrony with the external 24-h environment. Thus, the animal, or plant, is doing the right thing at the right time of the day or night such that optimum survival and reproductive success are ensured. A second, and less visible but no less important, type of synchrony imposed by the circadian clock is referred to as internal synchronization. In internal synchrony, the vast array of internal cellular, metabolic, physiological, endocrine, and behavioral rhythmic processes are maintained in temporal relationships to allow for life processes to be carried out at optimal efficiency. Until recently, this concept of internal synchrony was more often applied to the functioning of the organism as a whole. That is, in the case of

mammals, the SCN was seen as the master circadian clock regulating the timing of the various organ systems and behavior of the animal to ensure optimal internal synchrony for survival and reproductive fitness. In the case of humans engaged in shift work or experiencing jet lag, the internal synchrony would be perturbed (i.e., internal desynchronization), leading to less than optimal organ/behavioral performance. However, with the discovery that most if not all tissues and organ systems of the body have their own circadian molecular core machinery, the concept of internal synchrony takes on new meaning. One can now talk about internal desynchronization at the local cellular or tissue level. Such a paradigm shift in thinking about the meaning of internal synchronization has profound implications for health and disease.

The fact that the expression of hundreds of genes is under local (i.e., cellular) circadian control argues that the phase relationship between the rhythmic expression of these genes has functional significance at the cellular and/or tissue level. Just as a breakdown of internal synchrony at the macro-level (i.e., organ system/whole organism) is disruptive to health and well-being, one can expect that a similar breakdown at the micro-level (cellular/tissue) could lead to dysfunction at the local level. Thus, we may have a perfectly functioning circadian clock system at the macro-level, but still have a dysfunctional system at a local tissue level. Age-related diseases are often associated with tissue (CNS or peripheral) dysfunction due to age-related breakdown (e.g., due to oxidative stress, DNA repair dysfunction, accumulated protein/DNA damage) in cellular processes. However, the newly discovered circadian molecular clock machinery and its overall importance for cellular/tissue timing raises the intriguing possibility that many age-related diseases may have at their core a breakdown in the timing or internal temporal organization. Many diseases are due to malfunction of a particular tissue, organ, or organ system, whether due to external or internal factors, and death is often associated with whatever vital system breaks down first. An intriguing offshoot of this concept is that disease may be due to temporal disorganization at the cellular or tissue level, whether due to external or internal factors, and death may be due to the abnormal timing at the molecular/genetic level in specific tissue/organ systems whose normal function is critical for the survival of the organism. The recent finding that a mutation of a canonical circadian clock gene, *Clock*, can lead to a major disruption at tissue and behavioral levels in energy balance, as well as obesity and the metabolic syndrome, may be an example whereby temporal disorganization leads to disease conditions at the macro and micro organizational levels.

Appraisal Processes

Interpretive Bias

Attentional Bias

Assessment of the Cognitive Approach

Glossary

<i>Appraisal</i>	An evaluation of whether the situation is threatening and the availability of coping strategies.
<i>Attentional bias</i>	A tendency to attend preferentially to threat-related rather than neutral stimuli.
<i>Coping strategies</i>	A wide range of different ways of handling stressful situations, some focusing primarily on behavior and others on cognition or emotion.
<i>Interpretive bias</i>	A tendency to interpret ambiguous situations in a threat-related fashion.
<i>Transactional models</i>	A theoretical approach based on the notion that stress is determined by the interaction of the situation and the individual.

There is a consensus that stress responses (whether psychological, behavioral, or physiological) depend at least in part on various cognitive processes. More specifically, it is assumed that it is important to distinguish between the actual situation (defined in some relatively objective fashion) and the situation as it is perceived by the individual. There are systematic individual differences in the way any given threatening situation is perceived, and many of these differences can be understood by assuming that individuals differ in the cognitive processes determining how the situation is perceived or interpreted.

The emphasis on cognitive processes forms part of a reconceptualization of stress. The traditional view was that stress is an almost inevitable consequence of an individual's being exposed to a stressor (e.g., loud noise or complex situation). The contemporary

view (expressed with particular clarity by Lazarus and Folkman) is that stress should be considered in terms of transactional models. More specifically, whether any given stimulus or situation produces stress depends on complex interactions between the stimulus or situation and the individual's appraisal and coping processes. Cognitive appraisal is of major importance within this transactional approach because stress is experienced only when the individual perceives that environmental demands exceed his or her available resources.

Appraisal Processes

Most theoretical approaches concerned with the role of cognition in influencing stress responses emphasize the crucial role of appraisal processes. A seminal influence in this area is the contribution of Lazarus, who argued that cognitive appraisal is of central importance in determining individuals' reactions to threatening stimuli and situations. More specifically, he argued that cognitive appraisal can be subdivided into three forms of appraisal: (1) primary appraisal, in which the immediate situation is perceived as being positive, stressful, or irrelevant to well-being; (2) secondary appraisal, in which the individual takes into account the resources that he or she has available for coping successfully with the current situation; and (3) re-appraisal, in which the preceding primary and secondary appraisals are modified, if necessary, on the basis of ongoing monitoring of the current situation and the coping strategies being used by the individual.

There is a considerable amount of evidence demonstrating that manipulations of cognitive appraisal have significant (and predictable) effects on self-report measures of emotion and on psychophysiological responses. In addition, individual differences in spontaneous cognitive appraisals are predictive of stress responses. For example, Gaab and colleagues exposed participants to a simulated job interview and a mental arithmetic task in front of an audience. Their key finding was that anticipatory cognitive appraisal accounted for up to 35% of the variance in the salivary cortisol response.

Coping Strategies

Of crucial importance during secondary appraisal is a consideration of various coping strategies, which are

ways of dealing with a stressful situation. Examples include problem-focused coping, emotion-focused coping, and avoidance-based coping. Numerous coping strategies have been proposed. Indeed, in a 2003 review, Skinner and colleagues produced a list of 400 different coping strategies based on previous research. They produced a coherent structure for coping based on various systems put forward by earlier theorists. As a consequence, Skinner and colleagues placed coping strategies into a limited number of loosely organized core families of coping.

Interpretive Bias

The notion that cognitive appraisals are important in determining an individual's stress level has been applied extensively in the clinical field. In essence, it is assumed by cognitive therapists that unduly negative and pessimistic cognitive appraisals of environmental or internal threat-related stimuli and situations produce high levels of anxiety and stress in patients with anxiety disorders. The term interpretive bias is used to describe such pessimistic cognitive appraisals, and there is much evidence that anxious patients have interpretive biases for those stimuli and situations most closely associated with their particular disorder. For example, patients suffering from social phobia experience extremely high stress levels when anticipating or being involved in demanding social situations, and patients with panic disorder produce exaggerated responses when physiologically aroused.

The issue of causality is important. The finding that patients with anxious disorders have various interpretive biases could be due either to the possession of interpretive biases triggering or maintaining clinical anxiety or to being clinically anxious, causing the development of interpretive bias. Relevant evidence was discussed by Yiend and Mackintosh. Healthy individuals who were trained to select threat-related meanings of homographs responded to stressful videos with a greater increase in anxious mood than did those not receiving such training. Such findings indicate that interpretive bias can increase anxious and stressed responses to stressful situations.

Attentional Bias

Another way in which cognitive processes are related to stress and anxiety is via attentional bias, which is a tendency to focus attention on threat-related rather than neutral stimuli when both types of stimuli are present concurrently. Healthy individuals who are highly stressed or anxious and patients with anxious disorders exhibit attentional bias to a much greater extent than other people.

The association of attentional bias with stress and anxiety does not in and of itself demonstrate that attentional bias has causal efficacy in producing stressed and/or anxious states. However, this causal issue has been investigated in a number of recent studies. Two experimental approaches are of particular importance. First, attentional bias can be assessed in a group of individuals prior to receiving very stressful information, and the extent to which prior attentional bias predicts subsequent stress responses can be measured. This approach was adopted by MacLeod and Hagan, who studied women subsequently receiving a diagnosis of cervical pathology. The extent of attentional bias to subliminal stimuli predicted emotional reactivity after receiving the diagnosis.

Second, individuals can receive extensive training designed to increase or decrease attentional bias. For example, MacLeod and colleagues required participants to respond as rapidly as possible to probe stimuli that replaced one of two concurrently presented stimuli (one threat-related and the other neutral). Attentional bias was produced by consistently having the probe stimuli replace threat-related stimuli, and opposite attentional bias (i.e., avoidance of threat-related stimuli) was produced by consistently having the probe stimuli replace neutral stimuli. Participants who had been trained to produce an attentional bias showed enhanced negative emotional responses to a stressful task compared to those trained to produce an opposite attentional bias.

Assessment of the Cognitive Approach

Cognitive appraisal, interpretive bias, and attentional bias can take many forms and occur in a wide range of situations. For example, some appraisal processes seem to operate relatively automatically and below the level of conscious awareness, whereas other appraisal processes are conscious and deliberate. Another distinction is between appraisal processes that revolve primarily around the individual and his or her ability to cope with a stressful situation and appraisal processes that are strongly influenced by the prevailing social context. Most research in this area has focused on conscious appraisal processes based on the individual's assessment of his or her individually based coping strategies. As a consequence, there should be more emphasis in future research on socially based appraisal processes occurring below conscious awareness.

It is important to ascertain the limits of contemporary cognitive approaches to stress. Four potential limitations were discussed by McNally. First, sometimes appraisal-based approaches produce findings that appear almost tautological. For example, claiming that an individual feels stressed in a given situation

because he/she finds that situation threatening may seem almost self-evident. However, such a claim represents progress in the sense that it identifies cognitive processes as being intimately involved in stress responses, and it provides an impetus to discover more about the processes responsible for such an appraisal.

Second, much of what is known about appraisal processes and interpretive biases is based on self-report data. Self-report data are subject to various distortions and inaccuracies. In addition, individuals in stressful situations typically have only limited access to information about the precise factors causing them to produce certain cognitive appraisals or interpretive biases. It is undeniable that self-report data are limited in various respects. However, much research has included various measures not dependent on self-report; these include behavioral measures of interpretive and attentional biases and psychophysiological measures of stress responses.

Third, there are complex issues relating to causality. In spite of the evidence that manipulations designed to alter cognitive appraisals, interpretive bias, or attentional bias have predicted effects on stress and other responses, it is probable that causality can also operate in the opposite direction, with stress influencing cognitive processes.

Definition of Cognitive-Behavioral Therapy

Specific Techniques

Applications of Cognitive-Behavioral Therapy in the Stress Response

Glossary

Cognitive therapy
Exposure

A brief psychotherapeutic approach aimed at changing thinking.

A brief psychotherapeutic approach based on exposure to feared situations or stimuli.

Problem-solving training
Rational-emotive behavior therapy

A brief psychotherapeutic approach for improving problematic situations and/or interpersonal conflicts.

A brief psychotherapeutic treatment that relies on persuasion and reason.

Stress-management approaches

A set of diverse techniques for reducing psychophysiological activation.

Definition of Cognitive-Behavioral Therapy

The term cognitive-behavioral therapy subsumes a number of diverse therapeutic procedures, such as cognitive therapy, rational-emotive psychotherapy, problem-solving interventions, and exposure. In a restrictive definition, it indicates psychotherapeutic approaches that explicitly seek to produce change in cognition as a means of influencing other phenomena of interest, such as affect or behavior. This definition excludes specific behavioral interventions, such as exposure, that may work through cognitive mediation but that are not primarily intended to produce change by influencing thinking. A broader definition stems from the growing awareness that most psychotherapeutic approaches combine cognitive and behavioral elements, although in different ways and to different extents.

As a result, both cognitive and behavioral approaches may legitimately belong to the broader rubric of cognitive-behavioral therapy. In recent years there has been an increasing awareness of the common ingredients that pertain to the psychotherapeutic process (Table 1) and cognitive-behavioral approaches. The main characteristics that cognitive-behavioral therapies share are the following:

1. The therapy tends to be short (fewer than 20 sessions).
2. The therapy is structured and follows a pre-arranged schema of development.
3. The attention is centered on current problems.
4. Patient and therapist agree on the goals of treatment, which are clearly defined.
5. The patient is encouraged to perform self-observation of thinking and/or behavior, which may lead to their characterization (functional analysis).

Table 1 Nonspecific therapeutic ingredients that are shared by most forms of psychotherapy

<i>Ingredient</i>	<i>Characteristics</i>
Attention	The therapist's full availability for specific times
Disclosure	The patient's opportunity to ventilate thoughts and feelings
High arousal	An emotionally charged, confiding relationship with a helping person
Interpretation	A plausible explanation of the disturbed symptoms
Ritual	A ritual or procedure that requires the active participation of both patient and therapist and that is believed by both to be the means of restoring the patient's health

6. Homework assignments (whether consisting of self-observation or performing specific tasks) are given and reviewed by the therapist.
7. The therapy aims at developing the patient's control over his or her own problems or behaviors.

In randomized controlled trials, behavior therapy (exposure) alone and cognitive therapy alone resulted in similar improvements in obsessive-compulsive disorder, agoraphobia with panic attacks, posttraumatic stress disorder, and hypochondriasis. The fact that similar results can be achieved by different therapeutic approaches is leading to a weakening of classic paradigms and theories underlying each specific psychotherapeutic approach and to the necessity of paradigm shifts in our understanding of clinical changes. According to an evidence-based viewpoint, the term cognitive-behavioral therapy has a broad connotation and may indicate any brief psychological therapy that uses the ingredients listed above. The relative weight of each (or additional) ingredient may vary from one technique to the next, as defined by treatment protocols. In clinical practice, it may even vary from one case to another, or according to the stages of application of psychotherapy. Different ingredients may be used simultaneously from the beginning of treatment, or in a sequential order. For instance, in the cognitive-behavioral prevention of recurrent depression, behavioral techniques may characterize the first phase of treatment, whereas cognitive restructuring is applied only at a later point in time.

Specific Techniques

The therapeutic techniques that are used in cognitive-behavioral therapy may range from modification of emotional and relaxation responses (e.g., stress management techniques) to cognitive restructuring (e.g., cognitive therapy). The most important approaches (in terms of clinical acceptance and effectiveness or future implications) are the following:

1. Exposure
2. Response prevention
3. Operant conditioning
4. Relaxation
5. Stress-inoculation training
6. Problem-solving training
7. Rational-emotive behavior therapy
8. Cognitive therapy
9. Well-being therapy

Exposure (mainly graded, planned, homework exposure to distressing stimuli) has emerged as the most effective behavioral technique in anxiety disorders.

In the setting of disturbances such as obsessive-compulsive disorder, exposure to avoided cues may be associated with response prevention (staying in contact with those cues during the ensuing discomfort). Exposure appears to be a key factor in therapeutic change and may be implemented by diverse protocols, whose effectiveness, however, depends on the degree of *in vivo* exposure by the patient as a homework assignment. Operant conditioning derives from Skinner's work on the importance of contingencies in behavior, that is, whether a given response is followed by a positive or negative reinforcer. More than a specific strategy, it is a technique that may be incorporated in more complex strategies, such as dietary programs. Techniques based on relaxation methods achieved wide popularity in the 1970s and have been documented to be effective when emphasis is placed on enhanced muscular control, as in many cases of functional medical disorders. Relaxation may be seen as part of stress-management approaches that are aimed at reducing arousal and that combine various therapeutic ingredients, such as stress-inoculation training. This technique combines cognitive restructuring with behavioral self-management techniques. Patients are encouraged to apply these skills to a series of increasingly difficult tasks in order to cope with problematic life events. Problem-solving training emphasizes social problem solving as the primary coping strategy. This transactional approach uses a set of sequential procedures for dealing with problematic situations and interpersonal conflicts. In Ellis's rational-emotive behavior therapy, patients are taught to examine rationality as the primary mechanism of change. Beck's cognitive therapy is today probably the most widely endorsed cognitive intervention. Patients are encouraged to identify their beliefs, to treat them as hypotheses to be tested, and are taught alternative explanations. Both rational-emotive therapy and cognitive therapy incorporate behavioral components in their approach. Well-being therapy uses cognitive restructuring and behavioral interventions for enhancing psychological well-being. It is aimed at changing beliefs, attitudes, and behaviors that are detrimental to well-being.

Applications of Cognitive-Behavioral Therapy in the Stress Response

Cognitive-behavioral intervention may have two distinct yet ostensibly related roles in the modulation of stress response. One is concerned with a reduction in the psychophysiological activation that is associated (e.g., stress management approaches). The other is

related to the transactional model of stress, which emphasizes cognitive appraisal (how an event is interpreted by the individual) and coping (e.g., cognitive therapy). It may include supporting successful behavior change strategies to decrease health-damaging behaviors, increasing levels of social support, identifying physical symptoms that are expressions of emotional distress, and helping patients develop alternative coping strategies.

There is substantial evidence, based on randomized controlled studies, that cognitive-behavioral treatment may improve the outcome and quality of life of several psychiatric and medical disorders. Evidence-based applications of cognitive-behavioral therapy in psychiatric disorders include alcoholism and drug dependence, anorexia nervosa, bulimia nervosa, generalized anxiety disorder, hypochondriasis, mood disorders, obsessive-compulsive disorder, panic disorders and agoraphobia, personality disorders, posttraumatic stress disorder, psychosis and schizophrenia, simple phobia, and social phobia. Evidence-based applications of cognitive-behavioral therapy in medical settings include arthritis, asthma, cancer, chronic fatigue syndrome, chronic pain, coronary heart disease, diabetes, epilepsy, HIV infection and AIDS, hypertension, inflammatory bowel disease, irritable bowel syndrome, obesity, preparation for medical procedures, smoking, and tension headache. Further, it may improve health-promoting behaviors, such as changing harmful lifestyle patterns and habits and modifying illness attitudes and behaviors. In view of the role of psychological well-being in human health and disease, it is conceivable, but yet to be tested, that well-being therapy may offer another route to the improvement of the stress response. The absence of wellness may in fact create conditions of vulnerability to life's adversities, and an increase in psychological well-being may increase an individual's coping skills.

There is increasing evidence that cognitive-behavioral therapy exerts its effects by modulating the functioning of specific sites in limbic and cortical regions. It may thus work at the molecular level to alter stress-related gene expression and protein synthesis or to influence mechanisms implicated in learning and memory acquisition in stress-related neuronal structures.

Introduction**Problems with a Diagnosis of PTSD****Introduction**

Chronic stress reaction is appreciably different from the acute reaction described in a separate article. In the American and British militaries, dating from the American Civil War, a chronic stress disorder was generally what was referred to when medical personnel used terms such as soldier's heart, neurasthenia, battle neurosis, shell shock, traumatic neurosis, and battle fatigue. Of interest is that any of the above terms were literally ordered out of existence in the United States Army by General Omar N. Bradley in 1943. Colonel Long wrote: "Of the possible diagnostic

terms discussed, this term [combat exhaustion] was chosen because it was thought to convey the least implication of neuropsychiatric disturbance." Since the early 1980s this disorder has been frequently referred to as posttraumatic stress disorder (PTSD).

As in acute combat reactions, causes of the chronic condition are multiple. Military men developing a chronic reaction have typically been under combat stress for many weeks, months, or perhaps even years. Their physiological state appears to be characterized by hypoarousal. Instead of fight-or-flight physiology, these men tend to show signs and symptoms of conservation/withdrawal. The affected soldier frequently isolates him/herself from peers and shows signs and symptoms of depression. Once established, this chronic reaction is extremely difficult to reverse. In animal studies of defeat situations, a similar syndrome is seen. Signs and symptoms, predispositions, precipitants, treatment, and prevention of chronic combat reaction are outlined in subsequent sections of this article.

Signs and Symptoms

Early signs include impairment of previously displayed skills, severely lowered frustration tolerance, excessive griping, and even mild-to-moderate

paranoia. As these characteristics are frequently manifested in all combat troops, it can be a subtle distinction to determine when they exceed the normal range and signal concern. In sum, when these traits cause a human to significantly isolate him/herself from his/her peers and his/her military performance is substandard, it is time to evaluate the individual. If excessive alcohol or drug use, and/or signs and symptoms of depression are also part of the picture, the diagnosis should be strongly suspected.

If urine and blood samples could be collected in the field, catecholamines should be found to be at normal, or even low, levels in men with chronic combat reactions. In contrast, cortisol should be found to be significantly and persistently elevated throughout the circadian cycle. In a variety of chronic stress reactions, the baseline for cortisol secretion appears to be reset to a higher level. A further biochemical correlate of chronic stress is serum cholesterol. This high-density lipid is frequently seen in low serum concentrations during acute stress situations but shifting to high concentrations over a prolonged stress period (months to years).

In its most severe form, the soldier with a chronic combat reaction is so slowed in his/her thinking and motor movements that he/she appears to resemble a robot. His/her vacant-eyed look seems to focus far into the distance and has been labeled the 1000 yard stare. At this point the person is totally unable to function.

Predispositions and Precipitants

Many of the susceptibility factors making individuals more prone to chronic stress reactions are the same factors lending susceptibility to acute reactions to stress. These factors included childhood traumas, female gender, family and personal history for psychiatric

illness, minimal social skills, low levels of education, and antisocial traits. These traits are frequently accompanied by recent, pre-deployment, life stress.

Whereas intensity of battle is a major precipitant for an acute combat reaction, duration of combat is a large force shaping a chronic combat reaction. As in the acute disorder, high casualty rates add to the likelihood of this reaction. Frequently, a direct relationship has been seen between wounded-in-action rates and disabling chronic psychological reactions to combat.

A critical environmental precipitant is lack of mobility and/or progress in battle. This condition was widely prevalent during World War I, when trench warfare resulted in men spending up to 2–3 years in the same labyrinth of trenches and tunnels. In *Good-bye to All That*, British author Robert Graves wrote about his years in the trenches, where the war never seemed to progress and the only way out was to be wounded or killed.

An interpersonal precipitant is loss of confidence in leadership. If a mistake in tactics is made, for example a strike hits friendly forces, the soldier may then believe that his/her lack of confidence in command is justified.

On a personal level, when a soldier loses his/her sense of purpose, and especially when he/she perceives that there is no end in sight to long-lasting stress, the risk for this condition increases markedly. Preexisting neurosis and character pathology are personal factors which increase the liability of a soldier to develop a chronic stress reaction. As in acute battle stress, a severely dysfunctional early family life, possible abuse, lack of socialization experiences while growing up, and low educational attainment have been shown to predispose these individual to chronic battle stress reactions (Figure 1).

Figure 1 A presentation of selected early developmental and personal factors influencing susceptibility to symptom response following chronic stress.

Several resistance factors making reactions to stress less likely to occur are the opposite of susceptibility factors. These factors are a healthy childhood and a healthy family medical history, high school graduation, plentiful socialization when growing up, and an ability to find and give social support. Added to these factors are good leadership qualities, optimism tempered by reality, and an ability to pace oneself throughout a long campaign (Figure 2).

The progression of chronic stress reactions to recovery is approximately 40%, compared to a 60% likelihood of developing a subsequent development of a disorder. These subsequent disorders include several possibilities – not just chronic PTSD (Figure 3).

Treatment

The first line of treatment for PTSD is buddy and/or group support. This will be most effective in the early stages of the disorder. Even then, because the affected individual is constantly complaining and mistrustful,

it takes a strong commitment on the part of the group to bring him/her back into the fold. Such a group commitment has been seen to function extremely well in prisoner-of-war settings. Here, if buddy or group efforts failed to halt the withdrawal of a fellow prisoner, that person often died. The cause of death appeared to be chiefly determined by the person's loss of hope and giving up.

When specialized care is required for this condition, it means more time (from a few days to 3–4 weeks), more professionals (psychiatrists, psychologists, and possibly exercise therapists), and more resources (medications, a site for prolonged and specialized care) than is the case for acute combat reactions. The treatment site should be located near the front lines of battle but should be secure enough that it does not have to be moved frequently. The Israeli Defense Forces experimented with such a camp just inside their northern border during the Lebanon incursion. Here the men received medications (chiefly hypnotic and anxiolytic

Figure 2 A presentation of selected early developmental and personal factors influencing resistance to symptom response following chronic stress.

Figure 3 The progression of a chronic stress response to either recovery or to a psychiatric disorder with a more prolonged and uncertain course.

drugs), rest and replenishment, daily group therapy, and daily exercise sessions. This “walk ‘em and talk ‘em” approach resulted in return to duty rates between 40% and 70%.

Therapy may also include attempts to modify prebattle life stresses. If, for example, the individual is worried about the health of his wife or children, some communication (preferably by telephone) might be allowed. Personal visits, especially periods of home leave, are frequently a big mistake! This is because, once the person becomes enmeshed in his family setting his resolve to return to the front begins to weaken and his return to duty becomes increasingly unlikely.

In the long term, treatment of chronic combat reactions should include an appraisal of the person’s need for renewal. Often, job redefinition and/or retraining become appropriate. In animal studies of chronic stress, when conservation/withdrawal is seen, the animal becomes particularly motivated to learn new, and more adaptive, behaviors.

Today, treatment is routinely offered to soldiers returning from Afghanistan and Iraq – unlike the long delay in treatment that was the case for many servicemen from the Vietnam War. Dr. Michael Dinneen, a United States Navy psychiatrist, studied return to function of servicemen following their exposure to chronic stress. He emphasized that in assessing outcomes it is critical to know initial levels of functioning prior to the stress experience. If prior functioning was low, then recovery following stress meant a return to the low pre-existing level. Treatment following stress may well help these people make that recovery, as untreated individuals frequently develop PTSD (Figure 4). For individuals with moderate functioning prior to stress, early treatment not only helped them recover, but also often enhanced their pre-stress functioning (Figure 5). Lastly, for individuals with good

Figure 4 An illustration depicting a person’s functional outcome following stress dependent upon their prior functioning and if they received early treatment.

Figure 5 An illustration depicting a person’s functional outcome following stress dependent upon their prior functioning and if they received early treatment. Note the possibility of improved function with treatment.

Figure 6 An illustration depicting a person’s functional outcome following stress dependent upon their prior functioning and if they received early treatment. Note the possibility of mastering the experience with treatment.

prior functioning, early post-stress treatment often facilitated an improvement in their post-stress recovery to a “mastering” level (Figure 6).

Prevention

Most line commanders will strive to control environmental stresses such as fatigue, heat, cold, hunger, and sleep deprivation in their men. However, the maintenance of communication and morale in a situation of long and deadly conflict is no easy task. A tremendously important support mechanism for American prisoners of war in Vietnam was maintenance of communication. Via the chain of command, each man was given an important role to carry out in their ongoing struggle to survive with dignity.

Another important preventive measure is having predictable intervals set aside for rest and recovery. This may not be possible in some long-term battle

situations, but when it is, the effects are extremely salutary. Knowing that one would be rotated home 1 year to the day from arrival in Vietnam greatly assisted many soldiers in getting through their combat tours. It should be noted, however, that this policy also had undesirable effects, in that it inhibited group bonding and restricted a man's identity with his unit.

One interpersonal preventive measure frequently underemployed for combat troops is to allow for closure after a period of prolonged stress. Closure was inadvertently done well in the days of troop ship transport for soldiers returning from Europe and Asia following World War II. Aboard ship the men had ample opportunities to discuss their war experiences, compare their reactions with others, and to talk out several distressing thoughts and emotions. In a related manner, bringing men home as a unit markedly helps to prevent this disorder. Talking among trusted buddies on the return home is extremely supportive.

In terms of personal preventive measures, one of the most disturbing early stresses reported by prisoners of war was their awareness of all the things they had left undone prior to being taken captive. A soldier has enough to think about during the early stages of a long-term stress without additional concerns regarding the lack of a will, the lack of sufficient insurance, and other problems left for the family. This problem surfaced again in America's recent military engagements in Afghanistan and Iraq. Especially National Guard units, where their tours of duty were extended from initial order for 6 months up to 15 months of combat duty, were affected. These soldiers often discovered their jobs were no longer waiting for them, their families could no longer afford their quarters, children were ill, and so forth, and yet they did not know when they might go home.

Almost all persons experiencing chronic stress find physical fitness, especially of an endurance nature, to be of tremendous assistance. Endurance exercises not only help to pass time during periods of lull but also aid in maintaining feelings of vigor and well being. Of nearly equal importance is that exercise greatly facilitates sleep. Finally, a fitness program may even counter the tendency toward hypoactivity seen in chronic combat reactions.

Perhaps the single most important personal preventive strategy for long-term stress is developing a sense of pace. Prisoners of war and hostages held for 1 year or more testify to the critical importance of the acquired skill of taking one day at a time. Much like a mountain climber who slowly but relentlessly proceeds up the slope, a soldier must learn to pace him/herself so that sustained function is possible over many days, months, and even years. Also like the

mountain climber, some energy should be held in reserve. Occasionally, one has to draw upon this reserve in order to meet setbacks and/or unexpected demands. Personal traits of acceptance, humility, and humor can substantially facilitate this pacing.

A word should be said about the incredible importance of humor in prolonged stress situations. The ability to laugh, not only with others but also at oneself, is vital. Former prisoners of war have claimed that single instances of a humorous circumstance made them feel better for weeks to months later.

Personal beliefs, such as conviction of cause, faith, and basic optimism, are tremendously sustaining. Even if these personal characteristics are not present in individuals at the beginning of a prolonged period of stress, they can be developed – especially through supportive group interactions.

Problems with a Diagnosis of PTSD

Recovery from a chronic stress reaction occurs far more often than what it is generally believed to be the case. This misunderstanding is in large part due to today's habit of diagnosing both acute and chronic stress reactions as PTSD. Early following a trauma, victims can be plagued by intrusive memories and dreams of the trauma, tend to avoid reminders of their experiences and develop feelings of emotional numbing. If the victim subscribes to high numbers of these symptoms, with moderate-to-high intensities, psychological raters routinely diagnose PTSD. These evaluators are apparently unaware that persons with acute and chronic stress reactions describe very similar symptom pictures. A very recent investigation found that persons suffering from nontraumatic life events gave a higher PTSD symptom profile than did other subjects that had experienced traumatic events. Therefore, the symptom profile described above is not specific to PTSD.

Another problem with liberal use of this diagnosis is the common belief that no-one ever recovers from PTSD. One large element supporting this belief is that military veterans with this diagnosis often receive pensions for this diagnosis as long as they remain symptomatic. It literally pays the man or woman to remain disabled. Yet studies of severely traumatized military veterans, such as former prisoners of war, have found that over 90% of these men not only recovered from their torture experiences but also went on to live long and productive lives. A fuller description of how these former prisoners of war achieved such remarkable recoveries is presented in another article entitled: *Captivity, Recovery from*.

A third problem resulting from the trauma criterion for PTSD in the *Diagnostic and Statistical Manual of Mental Disorders, 4th edition* (DSM IV) was that it

was expanded from personally experiencing a major trauma to now including those who only witnessed it. With this definition, at least 200 000 000 Americans fulfilled this criterion after watching television footage of the 11 September 2001 terrorist attacks in New York and Washington, DC.

After years of just focusing on the trauma and the symptom picture, recent studies have introduced the importance of genetics, family medical history, past medical history, developmental factors, and resistance to stress – as noted above. Trauma by itself is a necessary, but not by itself sufficient, explanation of the etiology of this disorder.

Lastly, distortion and fabrication have entered the picture. A recent study of persons applying for a Veterans Administration pension for PTSD found that 52% of the applicants had either unclear evidence in their medical records of combat exposure, or no evidence at all of being in combat. Another 5% of applicants' military records showed that they had never served in Vietnam. A final 2% of applicants were found to have never been in the military. These six out of 10 applicants with little to no evidence of combat stress scored higher on their PTSD symptom profiles than did the four out of 10 applicants with clear evidence in their military files of combat exposure. A final complication was found for those who did serve in combat. Some of these men reported traumas more devastating than what actually occurred when their statements were compared to their military records.

These problems with compensation for Vietnam combat veterans should not cloud the fact that many individuals did, in fact, experience war or civilian traumas of extreme severity. Further, several of these people went on to develop long-lasting physical and/or psychological disabilities. It was also true that Vietnam veterans returning home did not receive the treatment for chronic stress outlined above. In particular, they came home quickly by jet aircraft, alone from their unit, and were frequently welcomed with spit and abuse from antiwar citizens that blamed them for the war. To their credit, the Veterans Association today offers immediate access to both physical and psychological evaluation and treatment for veterans involved in today's conflicts. The military also is alert to these needs for returning soldiers remaining

on active duty. As mentioned above, early medical and psychological treatment, with a goal of recovery, can prevent some of the prolonged disability seen in Vietnam era veterans.

Introduction

Combat Stress Reaction and Combat-Related
Posttraumatic Stress Disorder
Risk Factors for Combat Stress Reaction
Treatment of Combat Stress Reaction
Prevention of Combat Stress Reaction
Summary

Glossary

<i>Combat stress reaction (CSR)</i>	The acute psychological breakdown experienced by combat soldiers as a result of their exposure to the stress of individual, unit, and battle factors in the war zone.
<i>Expectation</i>	A treatment principle that states that psychiatric casualties should be treated with the expectation that soldiers will return to their unit.
<i>Immediacy</i>	A treatment principle that states that psychiatric casualties should be treated as soon as possible after symptom onset.
<i>Posttraumatic stress disorder (PTSD)</i>	A chronic pathological reaction following exposure to a traumatic event characterized by the intrusive reexperiencing of the traumatic event, the avoidance of stimuli associated with the traumatic event, a reduced responsiveness to the external world, and a range of autonomic and cognitive symptoms.
<i>Proximity</i>	A treatment principle that states that psychiatric casualties should be treated on or near the battlefield.
<i>Risk factor</i>	A variable that epidemiological evidence suggests is associated with an increased probability of a specific health outcome; the nature of this association is not necessarily causal.

CSR is an acute psychological breakdown experienced by combatants in a war zone. It is characterized by labile polymorphic manifestations ranging from overwhelming anxiety, irritability, and restlessness to psychological withdrawal, confusion, and psychomotor

retardation. Other characteristics include apathy, anxiety, depression, paranoia, conversion symptoms, signs of sympathetic arousal, and psychosomatic reactions such as diarrhea, abdominal pains, nausea, and vomiting. The defining criterion for CSR is that the soldier ceases to function effectively as part of his or her combat unit by acting in a manner that endangers his or her life and/or the lives of his or her fellow soldiers.

Introduction

CSR is a significant concern for the military because of its potential impact on the fighting effectiveness of combat units. It has been estimated that the ratio of psychiatric casualties to the number of soldiers killed and the number wounded in action during a battle of average intensity is 1 : 1 : 4. Belenky reported that the ratio of psychiatric casualties to wounded was 30 : 100 in the 1973 Arab-Israeli War and 23 : 100 in the 1982 Lebanon War. By way of comparison, the ratio of psychiatric to wounded casualties for the American army in World War II was 36 : 100. All these estimates attest to the significant impact of psychiatric casualties on the fighting capacity of a military unit.

For a number of reasons, the availability of scientific evidence on CSR is limited. In part, this is due to the difficulty of conducting prospective epidemiological investigations on the acute stress responses of combat soldiers during wartime. It is also a reflection of the elusive nature of CSR. That is, the polymorphic and labile nature of CSR means that clear diagnostic criteria cannot be developed. Another reason is that the introduction of the PTSD diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders* (3rd edn.; DSM-III) marshaled an extensive research effort into examining the long-term effects of combat exposure, particularly among U.S. veterans of the Vietnam War. Although the political and social factors driving this research effort were understandable, the voluminous research literature available on PTSD serves only to highlight the absence of empirical data on CSR. The only exception to this is a series of controlled studies on Israeli CSR casualties by Zahava Solomon and her colleagues. The aim of this article is to provide an overview of CSR by reviewing the literature on (1) the relationship between CSR and combat-related PTSD, (2) the identification factors for CSR, (3) the effectiveness of frontline treatment for CSR, and (4) the use of prevention programs to reduce CSR symptoms.

Combat Stress Reaction and Combat-Related Posttraumatic Stress Disorder

An adequate conceptualization of CSR must define the relationship between this acute reaction and the range of other stress responses that may be experienced by combat soldiers. Combat exposure can elicit a range of stress responses that can be divided into three categories: (1) a transient, nonpathological stress response, (2) CSR, and (3) PTSD. This division recognizes the need to distinguish between a soldier's adaptive response to combat stress and an acute or chronic reaction. An adaptive response is the manifestation of a transient stress response that is commensurate with the stress of daily life on or near the battlefield. CSR differs from a transient stress response in that it is an acute stress reaction that incapacitates soldiers to the degree that they can no longer function in combat. In some cases, CSR can be transient, with soldiers able to return to military duty after a few days rest from combat. In other cases, it may be the precursor to the development of combat-related PTSD. This form of PTSD is a chronic psychopathological stress reaction that occurs in soldiers after they have been exposed to a combat-related trauma. It should be noted that CSR is not a necessary precursor to the onset of combat-related PTSD. However, it has been suggested that CSR creates a latent vulnerability that can lead to the subsequent development of combat-related PTSD long after the war has ended.

CSR and combat-related PTSD are similar in that they share a number of common symptoms such as increased physiological arousal, startle reactions, restlessness, and psychological withdrawal. However, CSR differs from PTSD in that it may not necessarily develop following exposure to a specific combat event. CSR also differs in its symptoms of confusion, nausea, vomiting, and paranoid reactions. The critical pathological difference between these stress responses is that the symptoms associated with combat-related PTSD will endure. In PTSD, the symptom duration is expected to be at least a month, with the trauma being persistently reexperienced throughout the course of the disorder.

The relationship between CSR and combat-related PTSD has been extensively investigated in a series of studies examining the postwar adaptation of Israeli combat veterans. Solomon, Weisenberg, Schwarzwald, and Mikulincer assessed the prevalence and severity of combat-related PTSD in 382 Israeli CSR casualties 1 year after they had received treatment. Control group subjects were selected from those combat veterans who had fought in the same units as the CSR casualties but had not exhibited any symptoms or presented for

treatment. Matching with CSR casualties also occurred on the following variables: age, education, military rank, and assignment. The results showed that 59% of the CSR group developed PTSD, compared to 16% in the control group. There was also a significant difference in the number of PTSD symptoms reported. The CSR group patients reported a higher number of PTSD symptoms than their control group counterparts who also had PTSD. These findings suggest that those CSR casualties who develop PTSD experience a more intense form of the disorder than those combat veterans who develop PTSD without a history of CSR.

In a subsequent study, Solomon and Mikulincer found that 1, 2, and 3 years after the war, symptoms of combat-related PTSD were more prevalent among CSR casualties than among their matched controls. Similar trends were observed for social functioning, perceived self-efficacy in battle, and somatic complaints. The only reduction in the symptom levels observed during the study occurred when the intensity of intrusion and avoidance symptoms dropped substantially in the third year. However, the authors noted that this reduction in symptom levels should not be seen as evidence that the CSR veterans were getting better. These findings suggest that CSR casualties are more vulnerable to the subsequent development of combat-related PTSD.

Risk Factors for Combat Stress Reaction

The identification of risk factors for CSR is central to an understanding of the etiology of combat-related psychopathology. As discussed earlier, the epidemiological literature on Israeli combat veterans has shown that a higher percentage of CSR casualties subsequently developed PTSD than did controls with no CSR history. This suggests that an understanding of the risk factors for CSR may provide further insight into the factors associated with the development of chronic combat-related stress reactions such as PTSD.

The intensity of combat exposure has been identified as a significant risk factor for CSR. Belenky reported the findings from an Israeli Defence Force study that correlated objective measures of combat stress such as battle type and availability of tactical and logistic support with the incidence of physical and psychiatric casualties. This study found that battalions exposed to higher levels of combat stress had both a higher casualty rate and a higher ratio of psychiatric to physical casualties.

In addition to the intensity of combat exposure, there are a variety of other factors in the combat environment that may affect CSR onset. In a review of the clinical presentation of 158 U.S. army stress casualties during Operation Desert Storm, McDuff

and Johnson identified a number of environmental stressors associated with stress reactions. Although this study does not purport to be a systematic investigation of CSR risk factors, it demonstrated that a soldier's exposure to fatigue, cold, sleep deprivation, poor unit leadership, lowered morale, and threats to personal safety led to the onset or worsening of combat-related stress symptoms.

The identification of modifiable risk factors for CSR will play an important role in the development of effective prevention programs for combat soldiers. Despite this, there are few published studies that focus solely on CSR risk factors. A search of the recent research literature identified two controlled studies that investigated the association between a range of variables and CSR onset. Solomon, Noy, and Bar-On examined the association between demographic, military, and personality variables and CSR. One of the strengths of this study is that the researchers were allowed access to official military records in order to collect data on these variables. Age, education, combat suitability, military rank, and type of military service were identified as risk factors for CSR. These risk factors suggest that the onset of CSR can be accounted for by a combination of individual and situational factors.

This study found that 80% of the sample of psychiatric casualties were reservists. The psychiatric casualty rate for reservists was in marked contrast to the rate for career soldiers, which was the lowest of any of the groups studied. It appeared that a soldier's reservist status was a marker for a number of interrelated risk factors, all of which increased vulnerability to combat stress. Because the reservists were the oldest group of soldiers studied, the authors suggested that their age may have reduced their capacity to deal with the physical aspects of frontline service. Furthermore, reservists were more likely to have been exposed to combat in previous wars, which in turn may have reduced their capacity to cope with any subsequent exposure to combat stress. Being older, reservists were more likely to have established family and career commitments. These factors increased the stress on reservists when they had to adapt from civilian to military life. Also, in contrast to the career soldier, reservists had to make this change in a relatively short period of time. Solomon and Flum investigated the association between life events and CSR. They hypothesized that a combatant's exposures to stressful life events before the war may increase their vulnerability to CSR. However, the findings of this study did not provide support for this hypothesis. There was no relationship between the number, magnitude, or type of life events experienced by individuals prior to combat and CSR onset. However,

prewar life events were implicated in the subsequent onset of PTSD.

Treatment of Combat Stress Reaction

Frontline treatment interventions for psychiatric casualties are based on the principles of proximity, immediacy, and expectancy. These principles indicate that casualties should be treated in a setting close to the combat zone (proximity) as soon as possible after the onset of the CSR (immediacy) with the expectation that the soldiers will return to the frontline following their recovery (expectation). In the frontline setting, the main aim of treatment is to restore a casualties' depleted physiological condition by satisfying their needs for sleep, food, and drink. This usually lasts for a few days and takes place in an area of relative safety. During this time, casualties are provided with the opportunity to discuss their traumatic experiences.

One of the advantages of providing treatment on or near the frontline is that it allows casualties the opportunity to maintain their role as soldiers in a military unit. This enables access to their combat peers and opportunities for ventilation, which, in turn, reinforces the soldiers' sense of commitment to their combat unit. Another benefit of treatment in this setting is that it acts as a form of desensitization by exposing the soldiers to conditions similar to those that precipitated the CSR. Also, the immediate provision of treatment in the frontline places the expectation on the soldiers that they will be able to return to their combat duties.

Other principles of combat psychiatry that have been cited in the literature include simplicity and centrality. Simplicity refers to the use of uncomplicated treatments such as rest, food, and hot showers to provide the CSR casualty with a respite from the stresses of combat. Centrality refers to the process of assessing all CSR casualties at a central screening area so that an experienced team of mental health professionals can minimize the likelihood of inappropriate evacuations to the rear.

Although the principles of frontline treatment have been in use since World War I, it is only recently that the question of their effectiveness has been subjected to empirical investigation. Belenky highlighted the successful use of frontline treatment by the Israeli army during the Lebanon War, with 60% of CSR casualties returning to combat duties within 72 h. This return rate confirms the earlier findings of Solomon and Benbenishty, who investigated the relative contribution of proximity, immediacy, and expectancy in CSR recovery. Their study followed up 82% of the Israeli army CSR casualties of the Lebanon War to compare the effectiveness of frontline treatment

with treatment in a civilian setting at the rear (for security reasons, the precise number of subjects involved in this study could not be provided by the authors). Data on the immediacy and expectancy principles were collected through the use of self-report questionnaires. The outcome measures in this study were return to military unit and PTSD onset.

The results demonstrated a strong association between each of the frontline treatment principles and CSR casualties' unit return rate. A high percentage of CSR casualties who were treated at the front (43%) or near the border with Lebanon (59%) returned to their units. In contrast, a significantly lower percentage of CSR casualties returned to their units after being airlifted to the rear (21%) or treated in a civilian facility at the rear (28%). A high percentage of those soldiers who received treatment immediately after the onset of a CSR returned to their units (44%), whereas those who waited until after the war had ended before seeking treatment showed the lowest return rate (24%). Of the three treatment principles, expectancy displayed the strongest association with the unit return rate. CSR casualties who perceived that their therapist expected them to return at all costs had a higher unit return rate (53%) than casualties who were unclear about their therapist's expectations (26%).

The application of frontline treatment principles also had a significant impact on PTSD. Although the relationship between proximity and PTSD did not reach statistical significance, there was a strong trend suggesting that treatment proximity was a factor in the subsequent development of PTSD. When treatment occurred at the front or near the border, the percentages of CSR casualties who subsequently developed PTSD were 52 and 48%, respectively; when treatment occurred outside the war zone, this percentage increased significantly (66%). There was also a significant relationship between treatment immediacy and PTSD onset. In this study, the highest rate of PTSD (74%) was observed among those CSR casualties who had waited until after the war to seek treatment. Similar to the unit return rate findings, Solomon and Benbenishty reported a strong relationship between expectancy and PTSD. Casualties who perceived that their therapist expected that they would return to their unit at all costs exhibited the lowest rate of PTSD (55%).

Prevention of Combat Stress Reaction

Because combat is an unpredictable and chaotic experience, prevention programs for combat soldiers can only be formulated in general terms. The development of specific prevention programs targeting

CSR must address the complex interaction among individual, unit, and battle factors that determine a soldier's vulnerability to combat stress. These programs need to recognize that the occupation of combat soldier routinely exposes individuals to multiple stressful and/or traumatic events and that, over time, this reduces the soldiers' capacity to cope with combat stress. This is further complicated by the soldiers' perception of combat and their role in the war zone. Soldiers' subjective interpretations of a battlefield event as stressful or traumatic will be shaped by their acceptance of the violent nature of their occupation as well as by their previous experiences with such an event.

Prevention programs for CSR should also acknowledge that combat soldiers can be exposed to high levels of prolonged combat stress without ever being exposed to a specific traumatic event. This means that prevention programs that target specific mental health outcomes such as PTSD should not be seen as providing a complete alternative to the complex task of preventing CSR. As military personnel, combat soldiers also have to deal with all the normal occupational stresses that are experienced on a daily basis by the members of any large hierarchical organization in the civilian setting. It has generally been expected that, in the combat setting, the individuals most likely to experience this form of prolonged occupational stress, such as combat soldiers or medical personnel, will by virtue of their selection, training, and background be able to cope with the effects of their exposure.

The U.S. army's approach to the management of combat stress during Operation Desert Storm highlighted the importance of identifying and managing individual, unit, and battle factors in the onset of CSR. Examples of individual factors include combat experience, sleep, food, fitness, and stability of personal life. Also, soldiers' perceptions of their preparedness for combat, the loss of a family member at home, and/or a major threat to family during their service can affect their capacity to deal with combat stress. Unit factors include length of rest periods, the tactical situation, adequacy of supplies, communications, terrain, group cohesiveness, leadership, and morale. As noted previously, the intensity of combat exposure is a known risk factor for CSR. Specific examples of combat stressors include exposure to human suffering, risk of capture by the enemy, fear of torture, threat of personal injury, and death.

It is argued that prevention programs must target the range and type of combat stressors that soldiers are likely to encounter. Stress management techniques can be used to educate soldiers about the inevitability of experiencing fear during combat. The value of this experience should be emphasized, and soldiers should

be assisted in managing any anticipatory anxieties that they might have about maintaining control of their emotions in combat. Other stress management techniques such as problem solving, conflict resolution, and relaxation can also be used to strengthen soldiers' abilities to cope with the stressors that they are likely to encounter in the course of fulfilling their military duties as a combat soldier. These techniques can also be used by combatants who have the added responsibility of leadership to manage their own stress levels.

Military training provides an opportunity for the prevention of combat stress through the use of realistic training exercises. Using live ammunition, these exercises are designed to simulate the life-threatening challenges inherent in the combat experience. The successful completion of such exercises should increase soldiers' confidence in their ability to deal with the future stress of combat. As Oei, Hennessy, and Lim noted in their review of the literature on military training, the use of well-rehearsed drills during training exercises should lead to the development of automatic reactions in soldiers. When these are activated during combat, they reduce the level of cognitive demands on individuals, which in turn minimizes the effect of combat stress.

For military personnel who are in a support role, which may or may not involve active participation in combat, a general program of education about the likely occupational and interpersonal stresses that are frequently encountered in this setting would be beneficial. Based on the experiences of military personnel during the Vietnam War, this might include discussing (1) the problems associated with fighting an ambiguous enemy, (2) the definition of individuals' roles in the war zone, (3) a realistic appraisal of their contribution to the war effort, and (4) reasonable expectations of leadership.

Summary

CSR is an acute psychological breakdown that incapacitates soldiers to the degree that they are no longer able to function in combat. It is characterized by labile and polymorphic manifestations ranging from overwhelming anxiety and confusion to psychological withdrawal and psychomotor retardation. The variety of symptoms that are manifested during CSR has meant that clear diagnostic criteria have not been developed. Risk factors for CSR include the intensity of combat exposure, age, education, combat suitability, military rank, and type of military service. Treatment for CSR is based on the principles of proximity, immediacy, and expectancy. These treatment principles emphasize the need to treat CSR casualties

in a setting near the combat zone as soon as possible after symptom onset and with the expectation that the soldier will be able to return to combat after a brief period of rest and recuperation. The task of preventing CSR provides a complex challenge to military psychiatry. It requires an understanding of the interplay between a diverse range of individual, unit, and battle variables. Based on the evidence available to date, the use of realistic exercises during military training and the implementation of stress management techniques can play a role in minimizing the impact of combat stress.

Introduction

Acute Reactions to Combat Stress

Predispositions and Precipitants

Treatment

Prevention

Introduction

Disabling psychological reactions to stress, particularly to combat stress, have been witnessed frequently but codified differently in the various wars occurring over the past 150 years. Diagnoses coined for combat stress have varied from soldier's heart in the Civil War to shell shock in World War I to war neurosis and battle fatigue in World War II to combat stress in the Korean War and Vietnam conflict. In most instances, what was defined was either a precipitous or gradual breakdown in a serviceman's ability to perform his combat functions, accompanied by a variety of acutely distressing and/or chronically disabling mind–body symptoms.

Drawing from the military psychiatry literature, as well as from studies of human responses to stress encountered in a variety of civilian settings, a case can be made for distinguishing acute combat reactions from chronic ones. In so doing, clinical

presentations, predispositions, precipitating factors, treatment approaches, and expectations about return to duty become more specific.

Acute Reactions to Combat Stress

The Israeli Defense Forces in the 1980s and 1990s used the term battle shock to denote the acute and disabling psychological reactions to combat that appear within minutes to hours after stress exposure. In civilian settings, we find very similar conditions of acute stress reactions to trauma. These reactions are characterized by an abrupt onset of physiological hyperarousal following an exposure to an intensely stressful event(s) occurring during the previous hours, days, or weeks. The signs and symptoms of this disorder and its treatment are considered here.

Unsettling but manageable manifestations of this reaction are common to all humans facing trauma. It is, therefore, the degree of response rather than symptoms themselves that leads to a diagnosis. An early sign of vulnerability to military stress is a marked reluctance of the soldier to leave a secure setting. These people often are the last in line when heading toward danger, casting frequent glances back toward safety. They may unnecessarily check and recheck their equipment – these adventitious movements representing a displacement of anxiety. They may also show considerable difficulty understanding instructions and carrying out even simple tasks.

Widely opened eyes, dilated pupils, and tremulousness and rapid shallow breathing signal strong sympathetic nervous system activation. Sympathetic nervous system hyperarousal is the major physiological component of an acute stress reaction. When

blood or urinary measures for catecholamines are gathered from soldiers with this disorder, epinephrine and norepinephrine are both found to be significantly elevated. It is also likely that the soldier's serum cortisol is also elevated throughout this reaction.

As an acute combat reaction worsens, the affected soldier may not take cover during an assault, or he may remain hidden in a bunker and unable to fire his weapon or to care for a buddy in trouble. In its most severe form, affected individuals may show an overflow of undirected motor activity, which may mimic tics or seizures. Conversely, hyperarousal can also lead to a freezing of motor function, which may resemble paralysis.

An acute combat stress reaction can develop, and resolve, within a matter of minutes. Because recovery from this entity can be very rapid, the soldier may show a dramatic transition from gross panic at one instant to rational thought and behavior a few minutes later. Therefore, a cardinal rule is not to move an afflicted soldier further than the battle aid station closest to the front lines and assume there will be a rapid recovery.

Predispositions and Precipitants

It should be emphasized that no single factor by itself, even if the stress is tremendous, totally accounts for the development of an acute stress reaction. Rather,

it is the sum of separate forces acting in concert over a brief period of time. These forces usually include developmental factors, environmental conditions, and interpersonal stresses.

Developmental factors influencing susceptibility to acute stress response include childhood family traumas, especially abuse and neglect; poor socialization while growing up; low educational attainment; and little success in managing major life stresses (Figure 1). These individuals often join the military to escape from their troubled lives. The last thing they expect, and what their early lives has left them unprepared to handle, is to go into combat.

In contrast, resistance factors to acute stress reaction include enriched childhood and developmental experiences, prior stress experiences that the person handled successfully, high intelligence and educational achievement, plentiful social support, and prior training on how to handle stress (Figure 2). A positive attitude and an ability to resist rash behaviors are traits that enhance resistance to stress.

Environmental stresses, such as fatigue, hunger, sleep loss, cold, and heat, are common experiences of men in battle. They take on additional significance when other precipitants of acute battle stress co-exist, for example, when a battle is being waged in sustained heat (such as a desert war) and soldiers are dehydrated. The high magnitude of the stress situation, especially with a high casualty rate, makes stress

Figure 1 Early developmental and personal susceptibility factors for acute stress response.

Figure 2 Early developmental and personal resistance factors for acute stress response.

reactions more likely to occur. A surprise event leading to disorientation, concurrent illness, and poor physical endurance add even further to a susceptibility to acute stress response.

Interpersonal factors also contribute to susceptibility to stress, including recent life stresses outside of combat, such as family upheaval at home, financial problems, and difficulties getting along with peers. Reserve status, rather than a regular commission, and membership in a support unit (usually armor) are frequently an interpersonal precipitant of this disorder. Soldiers, who are members of elite units, in which the esprit de corps and morale are generally quite high, tend to perform far better in combat than men in less cohesive units. A further interpersonal stress occurs when reserves are brought forward to replace the dead and injured. These reserves may be assigned to tanks that are still bloody from the previous campaign and find themselves communicating, by radio, with people they have never met. A replacement soldier is seen as a new guy by the others and is a reminder that one of their buddies was killed or severely wounded. It may take weeks to months for a new soldier in a unit to lose this new guy label.

Factors of older age and inexperience are two additional interpersonal precipitants of this stress response. An infantryman in his late twenties or early thirties has a much higher probability of developing an acute combat reaction than one in his late teens or early twenties. Soldiers are especially vulnerable to acute stress reactions when they witness death for the first time. One of the major functions of military training is to prepare soldiers for the rigors of battle so that they can function almost reflexively in that environment. Yet it is impossible to train men for the experience of seeing their buddies killed.

Treatment

The treatment of an acute combat reaction should be immediate. It is far easier to reverse this reaction in its early stages than when the condition lingers. This means that the location where treatment is provided is usually at, or very near, the front lines of battle. Significantly, the person who carries out treatment is usually not a doctor; he is more likely to be a buddy or a medic/corpsman.

The most important first step in treatment is to help the affected individual gain control over his hyperaroused physiology. Rapid, shallow breathing will quickly cause hypocapnia with resultant light-headedness and feelings of panic. Hypothermia, hyperthermia, and tachycardia can produce similar effects. The

first rule in such a situation is to stop! Once the person begins to cool down (often literally), rational thinking can return. Having the affected person count slowly or make respiratory expirations last longer than inspirations is an easy remedy. When rational thinking returns, reorientation can take place and priorities can be reestablished.

An acutely stressed individual often has a need to talk about his recent trauma. A buddy or medic should listen to the story once, at most twice. Further recitations will have very little anxiety-reducing effect. Following one or two recitals, a soldier should be evaluated to determine if he is ready to be sent back to his unit (with a buddy) or needs rest and replenishment over the next 24 to 48 hours. These men can be treated at a battle aid station or in a separate section of a field hospital. Medications, if required, are generally hypnotics and anti-anxiety preparations. Because of this condition's ready reversibility, return to duty rates can be as high as 90%.

It has become a rule not to mix soldiers with disabling psychological reactions to combat with others who are physically wounded. When that occurs, men with psychological reactions quickly identify with the wounded and their psychological disabilities increase. A special effort must be made to keep these two classes of patients apart; otherwise, in the normal logistical flow of patients rearward, those with acute combat reactions will be separated from their unit. A special problem arises when a soldier experiences both an acute combat reaction and a physical wound. He is usually treated for the wound and not for his psychological condition.

In civilian settings, people with acute stress disorders should ideally be treated with psychiatric first aid. Groups of disordered individuals should be gathered in a large room such as a cafeteria. They should be able to sit around small tables and undergo a brief interview concerning their stress experience (again, no more than two recitals), sign a roster of attendance with home address and telephone, and be given some paper and a pen to write out their recent stress experience. Putting their stresses down in writing helps them to regain their concentration and reduces inclinations to repeatedly talk about their stories to others. Snacks should be available; foods high in fat, such as donuts, are most comforting. Doctors, nurses, and chaplains should act like they are social workers; that is, they should periodically circle the room asking victims if they have eaten recently, direct them to Red Cross personnel to inquire about family and friends, and to provide counseling as needed. When ready to leave the room, transportation to their homes should be facilitated if possible. It is

Figure 3 Acute stress response progression to rapid recovery or a psychiatric disorder with a more uncertain outcome.

counterproductive for psychiatrists and psychologists to set up an office and expect victims to come in for a lengthy session.

The good news about acute reactions to stress, including combat stress, is that they are short-lived and recovery from distressing symptoms is generally seen in 70–90% of affected people (Figure 3). A lasting disorder can occur in 10–30% of victims. Recovery from acute stress does not imply that disturbing memories of the event go away. Instead, several memories may persist during the person's lifetime. They do change from frequent awareness to distant recollections over time. However, during and shortly following a new and severe acute stress situation, these memories can make a renewed, and usually temporary, appearance.

Prevention

The environmental, interpersonal, and personal aspects of prevention should be considered as much as the precipitating event of this disorder in a multifactorial framework. It takes efforts in several areas to appreciably reduce the likelihood of acute stress reactions.

It is military doctrine to keep soldiers properly fed, warm, and rested whenever possible. When these conditions cannot be met, as is frequently the case in battle, command should realize that the chances for acute stress reactions are thereby increased. Although resupplies may not be under a commander's control, communications with his men regarding the progress of the campaign, the motivations and armament of the enemy, and so forth are certainly within his influence. Also, battle plans should be phrased in clear, concise, easy-to-remember language.

A most effective preventive force is realistic stress training. Seldom, however, is such training carried out. Perhaps the best example of preventive training that is currently performed is survival, evasion,

resistance, and escape training conducted by the U.S. Navy and U.S. Air Force. These 1–2 week programs are designed for aviators, who by the nature of their duties are at high risk for capture and prisoner-of-war status. However, realistic training for combat troops could also be provided. An important element of such training is allowing soldiers to actually experience panic symptoms under controlled conditions. The treatment steps of stopping and controlling hyperphysiology (allowing return of rational thinking and action) are then implemented. Also, mental rehearsal prior to stress training of the steps a soldier should follow in a panic situation should be part of this training.

Physical fitness leading to increased endurance leads to increased parasympathetic tone. Parasympathetic activation may well act as a brake on the sympathetic nervous system's hyperarousal during panic-producing situations. A soldier's personal commitment to the battle and attitude under stress are greatly shaped by his training. In civilian settings, a positive attitude, with realistic optimism can stave off a stress reaction. It was John Wooden, the eminently successful basketball coach at UCLA, who encouraged his players to "Be quick, but don't hurry." Such an attitude imparts a perception of personal control over fast-moving events.

Introduction

Research on stress and the common cold is a relatively new topic. The area was not reviewed prior to the 1990s, but since then it has become an important topic because it exemplifies many of the general features of the associations between stress and health, provides a good example of interactions between the brain, behavior, and the immune system, and has implications for life-threatening infectious diseases such as AIDS. Initial approaches to understanding the common cold used biomedical models in which the person was seen as a passive victim of exposure to the virus. However, the possible importance of psychological factors began to be considered, for two main reasons. First, when exposed to cold-producing

viruses, only a proportion of people develop the illness. Second, the severity and duration of symptoms vary widely among those who become ill. These two facts led to consideration of factors such as stress in the etiology and pathogenesis of the common cold.

A variety of measures of infection and illness have been examined in the research. Studies of infection have used virus isolation and antibody change as the outcomes. The severity and duration of the illness have been assessed using symptom checklists (e.g., runny nose, blocked nose, sore throat) and signs (e.g., weight of nasal secretion). Use of medication and the seeking of medical care have also been used as outcome measures. Different types of biological mechanisms by which stress may play a role in susceptibility to colds have also been proposed. Stress may alter the biological susceptibility (predispose some individuals). Second, it may trigger a process that increases virus replication (an initiating effect). Finally, it may contribute to an ongoing pathogenic process that leads to maintenance of the disease. As well as biological mechanisms, it has been suggested that stress may be associated with colds because it increases the perception of sensations in the nose, leads to these sensations being labeled as symptoms, and biases reporting the presence of illness. In addition, stress may increase use of medical care.

Before reviewing the evidence on stress and susceptibility to the common cold, it is necessary to consider some conceptual and methodological issues. Many studies of stress and the common cold are largely looking at correlations, and in some cases disease causes stress rather than vice versa. This problem is reduced in prospective studies, especially viral challenge research. Second, factors other than stress influence susceptibility: exposure; prior exposure (immunity); age, gender, social status; nutritional status; pregnancy; and biological rhythms (circadian, menstrual, and seasonal). Some of these may be correlated with both stress and infection and could, therefore, provide alternative explanations for postulated associations

between stress and colds. Each factor may also make an independent contribution to susceptibility to colds, and the more of these variables that are controlled, the greater the chance of showing effects of stress in the context of multiple environmental, social, and biological predictors.

Early Research on Naturally Occurring Colds

Cohen and Williamson reviewed the literature on stress and infectious disease. Some early research, using retrospective reports of stress, showed that the frequency and/or severity of upper respiratory tract infections (URTIs) are related to negative life events, upsets and worries, and personal failures. Other research has failed to demonstrate such effects, and some studies suggest that stress is just one of many psychosocial factors that have to be considered. Prospective studies, with measures of stress at baseline, have also provided some support for stress influencing susceptibility to URTIs. Diary methodologies have also been used. For example, Stone et al. found that undesirable daily events increased 3 to 4 days prior to an URTI episode, and events rated as desirable decreased 4 to 5 days prior to onset. One problem with such studies is that it is often unclear whether the effects are specific to URTIs or whether the results show that stress influences general illness behaviors. Other studies have included objective verification of the illness (either clinical diagnosis or virological assays), and, again, some of the research using these methods shows that stress influences susceptibility but other studies have produced negative results.

Virus Challenge Studies

A major problem with studies of naturally occurring colds is that they do not control for exposure to the virus. This has been overcome by conducting viral challenge studies. Early research using this approach produced conflicting results, which probably reflected the small sample sizes, lack of control of important predictors of infection, inadequate conceptualization of stress, and confounding effects of medication. These problems were overcome in a study by Cohen et al., carried out at the MRC Common Cold Unit, Salisbury, UK. The results of this study showed that susceptibility to colds was related to stress in a dose-response manner. This effect was still apparent when analyses controlled for possible confounding factors. It also appeared to be a general effect that was not

virus specific. Use of measures of infection then allowed analyses to be conducted to determine whether stress influenced susceptibility to infection or reporting of symptoms following infection. The results showed that perceived stress and negative mood were associated with increased risk of infection but that negative life events increased the likelihood of reporting illness after infection. It has often been suggested that stress influences health by increasing negative health-related behaviors (e.g., smoking, alcohol consumption). These factors were controlled for in this study, and the effect of stress could not be attributed to these (although both smoking and alcohol did influence susceptibility to colds).

Duration and Type of Stressor

Further studies of stress and susceptibility to colds considering the impact of different types of stressor have been carried out in the United States. The first major finding was that it is chronic stress that is important in increasing susceptibility to colds. It has also been shown that work stress (e.g., job insecurity) and interpersonal stress lead to the greatest risk of getting a cold. Other research has examined other psychosocial characteristics that may underlie or modify the effects of stress on susceptibility to colds. Social integration was found to be an important factor, with high social support being associated with a reduced risk of infection. Further analyses addressed the question of whether the reported effects might be attributable to personality characteristics, not to stress. Personality (extraversion) was found to be an important risk factor, but this effect was independent of those of stress.

Underlying Mechanisms

The review of the above studies confirms that stress is an important factor in susceptibility to the common cold, and the analyses have eliminated many alternative explanations such as health practices and other psychological characteristics. Further analyses have been carried out to determine whether the effects of stress are attributable to endocrine responses. High levels of both epinephrine and norepinephrine were associated with an increased risk of colds, but these effects did not account for the stress-colds association. Immunological mechanisms were also investigated, and it was found that the effect of stress did not reflect natural killer cell activity or antibody production. It is, of course, possible that other aspects of the immune system underlie the stress-colds effect (e.g., cytokines), but these require further investigation.

Another possibility is that stress influences local changes in the nose. There have been a large number of studies of stress and secretory IgA (sIgA). This is the most abundant immunoglobulin; it provides a barrier to invasion, and there is evidence that there is an inverse relationship between levels of sIgA and vulnerability to infection. Chronic stress suppresses levels of sIgA, which may be part of the explanation for the association between stress and susceptibility to colds. An alternative speculation is that stress has a direct effect on the nasal mucosa, which may lead to viruses becoming established and replicating at a faster rate. Further research is needed to address the effects of stress on the anatomy and physiology of the nose.

Conclusions

In conclusion, there is now strong evidence that stress influences susceptibility to the common cold. This has been demonstrated in studies that have controlled exposure to the virus and other confounding factors. Chronic stress is required to demonstrate these effects, and research has shown that work stress and interpersonal stress pose the greatest risk. Many possible mechanisms have been put forward to account for the association between stress and colds, and a large number of these can be discounted as the sole underlying mechanism. It is possible that stress influences many mechanisms and that it is the combined effects of these that is important. Alternatively, the effect of stress on susceptibility to colds may reflect specific changes to the upper respiratory tract rather than more central mechanisms.

Conceptualizing Life Stressors

Life Stressors and Adaptation

Stress Moderators

Integrative Models

Glossary

<i>Chronic stressors</i>	Stressors that endure over time, such as ongoing problems in a marriage and long-term difficulties with a troublesome supervisor at work.
<i>Coping strategies</i>	Cognitive and behavioral efforts to reduce or adapt to stressful conditions and associated emotional distress; most approaches distinguish between strategies oriented toward approaching and avoiding the problem.
<i>Life change events</i>	Stressors that occur at a discrete point in time, such as the death of a family member or losing one's job.
<i>Life crises and traumas</i>	Qualitatively more severe stressors, such as natural disasters or being the victim of a violent crime, such as rape.
<i>Personal resources</i>	Relatively stable personality and cognitive characteristics that operate as stress moderators, such as dispositional optimism and self-efficacy.
<i>Social resources</i>	Social factors that operate as stress moderators, such as emotional support and assistance from family members and friends.
<i>Stress moderators</i>	Personal and social resources and coping strategies that function either as protective or vulnerability factors when stressors occur.
<i>Stress resistance</i>	Individuals' adaptive capacity for resilience and constructive action in the face of challenge, emphasizing protective factors that can moderate the effects of stressors.

Conceptualizing Life Stressors

Community studies of life stressors investigate (1) life change events, (2) chronic stressors, and (3) major life crises and traumas (see [Table 1](#)). It should be noted that, although life change events and traumas have an acute onset, they often initiate chronic stressors, such as persistent economic and family problems. In fact, these enduring secondary stressors may account for many of the adverse effects of acute stressors.

Life Change Events

Initially, community studies of life stressors focused on acute life change events, which occur at a discrete point in time, such as the death of a close friend or losing one's job. Life change events generally are indexed by self-report questionnaires that may use objectively weighted life change units to reflect the relative level of adaptive demand associated with a particular life event. These weighted life change units are summed to reflect cumulative life change during a given period of time, typically the previous 12 months. Investigators also use in-depth interviews that, although time consuming, are able to assess the personal meaning of life changes. Although initial studies assumed that all life change, whether positive or negative, involved adaptive demands that were detrimental, later research revealed that the adverse health effects of life change are specific to negative life events. Later studies also showed that weighted life change units contributed little beyond an unweighted sum of events experienced in predicting illness. Based on these findings, most contemporary research on life change

Table 1 Major categories of life stressors with representative stressors^a

<i>Life change events</i>	<i>Chronic stressors</i>	<i>Major crises and traumas</i>
Divorce	Family role strain	Victim of natural disaster
Death of a close friend	Work role strains	Life-threatening illness
Legal problem	Ongoing caregiving demands	Personal war exposure
Fired at work	Ongoing financial problems	Victim of violent crime

^aAdapted from "Stress," Holahan, Ragan, & Moos, 2004, in Spielberger (Ed.), *Encyclopedia of Applied Psychology*, San Diego, CA: Academic Press. Copyright 2004 by Elsevier Science (USA).

events uses the sum of negative events experienced during a given period of time.

Chronic Stressors

Early community studies of life stressors were limited by their narrow focus on acute stressors. Eventually, recognizing that many life stressors are ongoing, investigators began to examine chronic stressors, which endure over time, such as social role strains and everyday hassles. Researchers studying social role strains often measure chronic family or work difficulties. Moreover, there has been a growing research interest in role strains associated with the interface between work and family life. Some stress studies have focused on additional burdens that often are associated with family life, such as caregiving for a chronically ill family member. For example, increasing interest is being devoted to caregivers of older family members suffering from Alzheimer's disease. Investigators have also studied minor life stressors that are experienced chronically, such as everyday hassles with troublesome neighbors or traffic problems. Increasingly, studies in this area also examine the health consequences of ongoing macrostressors, such as discrimination, national or regional economic recessions, and the ongoing threat of terrorism. As with acute stressors, the unweighted sum of these types of ongoing stressors provides an index of cumulative chronic stressors during a given period of time, typically the previous 12 months.

Major Life Crises and Traumas

In addition to indexes of cumulative stressors, community studies also focus on specific major life crises and traumas, which are qualitatively more severe than life events or role strains. For example, researchers have studied natural disasters, such as Hurricane Andrew in Florida; technological disasters, such as the Three Mile Island nuclear accident in Pennsylvania; and acts of terrorism, such as the destruction of the World Trade Center in New York. Current community studies also focus on how people cope with serious medical illnesses, such as heart disease, cancer, and diabetes. Interest in traumatic stressors is evidenced by a growing body of research on posttraumatic stress disorder (PTSD), a debilitating anxiety-based disorder caused by personal experience of a life-threatening stressor. Initially, PTSD research focused on stressors such as exposure to war as a civilian or soldier or being the victim of a violent crime such as rape. Over time, the definition of trauma has been broadened to encompass witnessing events that

place others at risk of death or serious injury or witnessing individuals being badly injured or killed by such events.

Life Stressors and Adaptation

Initially community studies focused exclusively on the adverse health effects of life stressors. Eventually, however, the research focus broadened to encompass adaptive processes of stress resistance and stress-related growth.

Stressors and Illness

Findings with diverse community samples have shown that negative life change events are associated with psychological stress reactions that involve depression and anxiety. Interpersonal problems and losses are especially likely to be associated with depressive reactions and threatening events with anxiety. Even though chronic stressors may be less severe than acute life events, their effects may last longer and be more pervasive. Thus, chronic stressors generally are more strongly linked to psychological distress than are acute life change events. More severe trauma exposure produces a recognized pattern of PTSD symptoms, including psychologically reexperiencing the trauma through flashbacks and nightmares, emotional numbing, and heightened arousal.

Life stressors may elicit physiological stress reactions (e.g., circulatory, digestive, and musculoskeletal problems) that are mediated through the activation of the sympathetic nervous system. In addition, life stressors are associated with susceptibility to less serious infectious diseases (e.g., colds, influenza, and herpes) and possibly to the onset and exacerbation of autoimmune diseases (e.g., rheumatoid arthritis). Underlying these latter findings is an apparent correlation between life stressors and both cellular (e.g., reduced lymphocyte proliferation) and humoral (e.g., decreased antibody production) indices of immune suppression.

Stress Resistance

Despite the consistency of these stressor effects, they typically account for only a small portion of the variance in illness. Moreover, individuals showed highly variable reactions to stressors; many people remain healthy despite being exposed to stressful circumstances. These findings engendered a new approach to conceptualizing the stress and coping process, described as stress resistance. From an initial emphasis on people's deficits and vulnerabilities, contemporary

community studies of life stressors have evolved to place increasing emphasis on protective factors that can counteract the potential adverse effects of life stressors.

A guiding assumption of stress resistance research is that personal and social resources and adaptive coping strategies can help individuals to manage stressful circumstances effectively and to remain healthy when stressors occur. Stress resistance research fundamentally changed the underlying assumptions that guided early investigators' conceptualization of the stress process. From initially placing an emphasis on people's deficits and vulnerabilities, stress research progressed to placing increasing emphasis on individuals' adaptive strengths and capacity for resilience and constructive action in the face of challenge.

Stress-Related Growth

Stress researchers have also come to recognize that life stressors can be constructive confrontations that challenge an individual and provide an opportunity for personal growth. Individuals may emerge from a stressful experience or life crisis with greater self-confidence, new coping skills, closer relationships with family and friends, and a richer appreciation of life. Stress-related growth can occur even when stressors involve profound adaptive demands, such as serious financial setbacks and the deaths of friends or family members. Of course, beneficial outcomes to life crises may emerge only after an initial stage of emotional distress and disorganization. Yet many people are able to grow stronger in the face of adversity.

Approximately half of women who experience a marital breakup show long-term improvements in psychological functioning. These women may become more assertive, develop more realistic views of themselves, and experience increased self-esteem with successful new careers. Similarly, survivors of serious illness often show more concern for and sense of community with others, a change in focus from the constant pressure of work to family relationships, and heightened awareness of religious and humanitarian values. Even in the context of stressors as profound as being a prisoner of war, a diagnosis of terminal illness, and the death of a close family member, some individuals are able to grow stronger, richer, and more caring.

Stress Moderators

Contemporary interest in adaptive outcomes in the stress process has encouraged efforts to identify factors that moderate the health effects of life stressors. Investigators have focused on the stress-moderating

roles of personal and social resources, coping strategies, and personal agendas.

Personal and Social Resources

A variety of relatively stable personality characteristics operate as protective factors that can help individuals remain mentally and physically healthy when stressors occur. Personality characteristics that relate broadly to personal control, such as dispositional optimism and self-efficacy, are especially important. Individuals who are more optimistic about the eventual outcome of a stressful experience and those who are more confident in their ability to manage adaptive demands manage stressful episodes more successfully than individuals who lack these personal strengths. In contrast, negative personality characteristics, such as neuroticism and low self-esteem, can operate as vulnerability factors that increase health risk under high stressors.

Social resources also play a key role in protecting individuals from the potential adverse effects of life stressors. Social resources include guidance and assistance from one's family members, friends, and broader social network. Emotional support, such as the nurturance of a caring family member or attentive listening of a trusting confidant, is especially important as a protective factor during stressful times. Of course, social ties are complex and may entail criticism or competition as well as support. In fact, studies that consider both the positive and negative aspects of relationships show that negative aspects of relationships are at least as strongly related to poorer adjustment as positive aspects of relationships are related to better adjustment.

Box 1 The *Life Stressors and Social Resources Inventory* (LISRES) provides a comprehensive picture of the interrelated stressors and social resources in a person's life. The inventory includes nine indices of life stressors and seven indices of social resources. **Figure 1** shows an illustrative LISRES profile for a 66-year-old woman with rheumatoid arthritis (scores are standardized, with a mean of 50 and a standard deviation of 10). Although she reported well above-average physical health stressors, she had below-average stressors in six of the other seven domains. Moreover, she also had above-average social resources in her work setting and in her relationships with her spouse, extended family, and friends. At an 18-month follow-up, this favorable balance of moderate stressors and high resources enabled her to manage quite well; she reported high self-confidence and below-average depression.

Moos, Ph.D., Copyright 1994 by PAR, Inc. Further reproduction is prohibited without permission of PAR, Inc.

Coping Strategies

A large number of community studies has examined the role of coping strategies in stress resistance. Coping encompasses cognitive and behavioral efforts to reduce or adapt to stressful conditions and associated emotional distress. Most conceptualizations distinguish between coping strategies that are oriented toward approaching and confronting the problem and strategies that are oriented toward reducing tension by avoiding dealing directly with the problem (see Table 2). People who rely more on approach coping strategies, such as problem solving and information seeking, tend to adapt better to life stressors. In contrast, avoidance coping strategies, such as denial and wishful thinking, generally are associated with more psychological distress.

Although we can draw overall conclusions about the relative efficacy of approach and avoidance coping strategies, such generalizations oversimplify the process of adaptation. Adaptation is best when coping efforts match situational demands. Individuals who are flexible in their choice of coping should show better adaptation than people who have a more restricted or rigid coping repertoire. Avoidance coping may be adaptive in the short term with time-limited stressors, such as pain, blood donation, and uncomfortable medical diagnostic procedures. However, avoidance generally is maladaptive as a long-term coping strategy. The manageability of a stressor also shapes coping effectiveness; approach coping processes are most effective in situations that are controllable.

Table 2 Four basic categories of coping strategies along with eight associated coping subtypes^a

<i>Basic coping categories</i>	<i>Coping subtypes</i>
Cognitive approach	Logical analysis ("Did you think of different ways to deal with the problem?") Positive reappraisal ("Did you think about how you were much better off than other people with similar problems?")
Behavioral approach	Seeking guidance and support ("Did you talk with a friend about the problem?") Taking problem-solving action ("Did you make a plan of action and follow it?")
Cognitive avoidance	Cognitive avoidance ("Did you try to forget the whole thing?") Resigned acceptance ("Did you lose hope that things would ever be the same?")
Behavioral avoidance	Seeking alternative rewards ("Did you get involved in new activities?") Emotional discharge ("Did you yell or shout to let off steam?")

Personal Agendas

An individual's personal agendas in the domain in which a stressor occurs shape the meaning and impact of the stressor. People function in multiple environments that often reflect different personal needs and commitments. Individuals appraise life stressors in the light of these personal agendas, and such appraisals can either enhance or reduce the stressfulness of a situation. For example, because chronic stressors provide a context within which new acute events are interpreted, they may alter the threshold at which events have negative impacts on health. Job loss during a period of bereavement may adversely affect health in part because it amplifies a more pervasive sense of personal loss.

Similarly, when an event threatens or disrupts a domain in which a person has central commitments, that event is more likely to have an adverse outcome. For example, women who experience a new severe event in a life domain in which they have marked difficulties, or in a domain that matches an area of marked personal commitment, are more likely to develop depression than are women who experience a new severe event in some other domain. At the same time, strong commitments can sustain coping efforts in the face of profound obstacles, such as coping with bereavement or a life-threatening illness.

Integrative Models

Most recently, community studies have been examining integrative frameworks reflecting reciprocal links among stressors, resources, coping, and adaptation. Integrative models have addressed how maladaptive behavior generates life stressors, the role of stressors in eroding protective resources, and how protective factors operate together in a mutually supportive way.

Stress Generation

In a revision of traditional conceptualizations of the stress process, the stress generation model describes how depressed individuals, through their depression and related behaviors, generate life stressors, particularly interpersonal stressors. These stressors, in turn, are linked to increases in subsequent depressive symptoms. The stress generation model has been applied across diverse age groups to predict depressive outcomes in both clinical and nonclinical samples. An association between depression and subsequent stressors is evident for both acute events and chronic strains. In a similar way, avoidance coping is prospectively linked to both acute and chronic stressors, independent of depression. Cognitive avoidance may permit incipient stressors, such as financial problems, to worsen. Behavioral avoidance may actively promote new stressors, such as when emotional discharge aggravates strains in family relationships.

Resource Depletion

Another set of community studies has examined a support deterioration model that describes how life stressors can deplete psychosocial resources. Research on natural disasters, combat, and caregiving has shown that stressors can deplete both personal and social resources. Resource depletion may be tangible and intrinsically tied to a stressor; loss of income or loss of a loved one entail real reductions in resources. However, resource depletion also has a cognitive component; perceived support appears to be especially vulnerable to deterioration after crises. Support diminishes after the immediate crisis period even though crisis victims face enormous ongoing demands. Moreover, in community-level disasters, individuals who could potentially provide support are often crisis victims themselves. Resource loss may help to explain the association between life stressors and a decline in psychological functioning. For example, disaster-related stressors deplete perceived support; in turn, this loss in perceived support mediates the connection between initial stressors and later depression.

Coping Mediation

Resources models of coping examine how personal and social resources relate to better functioning under high stressors by fostering adaptive coping efforts. At one level, these models identify a key mechanism through which personal and social resources operate; at another level, they demonstrate that adaptive coping requires a strong underlying psychosocial foundation. Among community adults facing high stressors, adaptive personality characteristics and family support operate prospectively as coping resources; in turn, coping mediates between initial resources and later health status. Similarly, among women coping with breast cancer and students adjusting to law school, more adaptive coping efforts operate as a mediator through which optimism relates to better psychological adjustment. People with higher levels of self-efficacy, for instance, tend to approach challenging situations in an active and persistent style, whereas those with lower levels of self-efficacy are less active or tend to avoid such situations. Social resources can enhance coping efforts by bolstering feelings of self-confidence, as well as by providing informational guidance that aids in assessing threat and in planning coping strategies.

Comorbidity and Stress

Major Depression, Substance Use Disorders, and Stress

Conclusion

Glossary

<i>Comorbidity</i>	The concurrence within the one individual of a substance use disorder and another psychiatric disorder.
<i>Dopamine</i>	A catecholamine neurotransmitter central to reward processes and psychiatric disorders.
<i>Mesolimbic dopamine pathway</i>	The trajectory within the brain of dopamine-releasing neurons from the ventral tegmental area to the nucleus accumbens, amygdala, hippocampus, and other related regions.
<i>Nucleus accumbens</i>	A brain region rich in dopamine neurons and believed to integrate reward responses and to be affected in substance use disorders.
<i>Substance-use disorder (SUD)</i>	The repeated uncontrolled use of a substance resulting in deleterious health and social outcomes; there are two forms, dependence and the less severe abuse.

Introduction

Comorbidity simply refers to the concurrent presence of two or more discrete disorders in the one individual. In psychiatry, it refers to at least one disorder being a recognizable *Diagnostic and Statistical Manual for Mental Disorders* (4th edn.; DSM-IV) or *International Classification of Diseases* (10th edn.; ICD-10) diagnosis and the second or subsequent disorders being either a physical medical illness or another psychiatric disorder. Commonly, however, the second disorder is substance-related, and it is in

this context that comorbidity (also referred to as dual diagnosis) is discussed here.

Substance-related disorder refers to the consumption of a substance by an individual resulting in deleterious health, social, or psychological outcomes. This definition allows the exclusion of substance use within culturally determined or religious domains and the recognition that some substance use may not necessarily be harmful depending on the substance and volume of use. Nevertheless, this definition encompasses a broad and heterogeneous group of disorders that can be applied to any particular substance. These disorders can be classified into disorders induced by the substance and disorders of the regulation of substance use. The first category includes intoxication, withdrawal, and those disorders that mimic other psychiatric disorders: deliriums of intoxication and withdrawal; dementia; amnestic, psychotic, mood, anxiety, and sleep disorders; and sexual dysfunction. The second category incorporates dependence and abuse. Dependence, which is considered more severe than abuse, comprises three or more of the following: tolerance (needing an increased amount of the substance for the equivalent effect or a diminished effect with same amount), withdrawal (physiological response to the reduction of substance use), prolonged or excessive ingestion, unfulfilled desire to reduce use, excessive time spent on substance use to the detriment of other activities, and use in spite of deleterious health effects. Abuse emphasizes the persistent use of the substance in the face of work, social, or forensic problems when the criteria for dependence are not met.

Commonly used substances include alcohol, caffeine, nicotine, cannabis, amphetamines, opioids, cocaine, hallucinogens, phencyclidine and ketamine, inhalants, and benzodiazepines; most commonly the use of more than one substance (polysubstance use) is observed. The pattern of substance use generally follows social criteria so that legal substances, such as alcohol, nicotine, and caffeine are most widely used, followed by decriminalized substances, and then by the most readily available illicit substances. For example, alcohol-use disorders are relatively less common in religious and social groups that prohibit its use.

When we combine these lists of disorders and substances, a large number of permutations for substance-related disorders is possible. All substances must induce intoxication; however, not every substance causes every other disorder. This is dependent on its individual pharmacodynamic and pharmacokinetic properties and, thus, it is critical to emphasize the differences in

the individual behavioral and neurobiological effects of each substance and their interaction with other psychiatric disorders. For example the sedating and myorelaxant properties of benzodiazepines contrast with the stimulating effects of amphetamine.

Given that comorbidity refers to coexisting but discrete disorders, the relationship between the disordered regulation of substance use and other psychiatric disorders and stress is of primary relevance here; SUD is used here to refer to disorders of substance-use regulation, namely dependence and abuse. This article outlines the observed relationships between SUD and other psychiatric disorders. It discusses the possible nature of these relationships with reference to the role of stress and details this in reference to major depression because of the well-documented effect of stress on relapses of both SUD and major depression.

Prevalence of Comorbidity

The lifetime prevalence of SUD in the general community has been estimated to be 16.7% (excluding nicotine and caffeine); the 12-month prevalence figures for any mental disorder is 26.2%. Thus, even if no relationship existed between the two clusters, comorbidity would be predicted to be 4% by chance alone. The reality is, however, that approximately 76% of men and 65% of women with SUD also have an additional psychiatric diagnosis, most commonly that of another SUD. Other, non-SUD psychiatric diagnoses also occur at rates greater than in the general community, and the reciprocal relationship is also true, suggesting that the two clusters of disorders are not independent. This high rate of comorbidity needs to be considered within the context of the various methods of ascertainment used (retrospective or prospective, structured interview, self-report, or caregiver report), the diagnostic systems used (DSM-III, DSM-III-R, DSM-IV, or ICD-10), and the sample populations (urban or rural; and psychiatric inpatient, outpatient, general community, drug treatment program, or correctional facility). This limits the extent to which studies may be compared across regions or over time. Given the diversity of substances and co-occurring disorders, the prevalence of comorbidity inevitably differs by diagnostic classification. Notwithstanding this, the incidence of comorbidity appears to have increased over the past 2 decades. In 1980 the United States National Center for Health Statistics reported that 12% of psychiatric inpatients treated that year had a SUD in addition to a non-substance-use psychiatric disorder. A decade later, the Epidemiological Catchment Area (ECA) study recorded that 48% of individuals with schizophrenia had a lifetime diagnosis of SUD. Subsequent estimates

of the prevalence of such comorbidity range from 35 to 53% in community and inpatient settings, respectively. It is noteworthy that epidemiological surveys that estimate the lifetime and 12-month prevalence of psychiatric disorders in the general population such as the 1990–1992 National Comorbidity Survey (NCS) and the 2001–2003 NCS-2 and NCS-Replication have enabled the analysis of comorbidity rates unbiased by sample selections of affected individuals. These surveys, however, are also limited in that they underrepresent several population segments such as the homeless or those in institutions. The examination of the so-called low-prevalence psychotic disorders is also excluded. It is unsurprising, therefore, that prevalence estimates of comorbidity from community population surveys are generally lower than seen in clinical settings.

Substances

Unfortunately, unraveling comorbidity is complicated by polysubstance use, particularly of alcohol with other drugs. According to the NCS, 78% of alcohol-dependent men and 86% of women met the criteria for a lifetime diagnosis of another psychiatric disorder, including drug dependence. Furthermore, although demographic characteristics such as male gender, younger age, less education, history of incarceration, and symptoms of conduct disorder and antisocial personality disorder predict substance misuse, these are not consistently associated with the types of substances misused. For example, age is related to lifetime prevalence of cannabis and cocaine but not alcohol-use disorder. In addition, attempts to find demographic or clinical correlates related to the order of onset of substance use and psychiatric disorders have not detected consistent differences to demonstrate a causal relationship. A key point to note is that no psychiatric diagnosis is exclusively related to a specific type of SUD.

Alcohol

Consistent across several studies, alcohol is the most commonly abused substance (when nicotine and caffeine are not measured), followed by cannabis. Among individuals with psychotic illnesses, approximately 39% of men and 17% of women had a lifetime diagnosis of alcohol abuse or dependence compared with a 12-month prevalence in the general population of 9% and 4%, respectively (National Survey of Mental Health and Well-being). These data concur with the ECA study, which found that 47% of those with schizophrenia spectrum disorders met the criteria for at least one comorbid SUD (34% for alcohol, 28% for any

drug use disorder). A high rate of alcohol comorbidity with affective illness is also described with adverse outcomes of mood destabilization and induction of depressive or manic episodes. In their 1990 review of studies on hospitalized alcoholics, Merikangas and Gelernter found that depressive symptomatology ranged from 16 to 59% and that this met a diagnosis of secondary major depression in 8–53% of cases. Although there is a consensus that a high comorbidity of alcohol abuse/dependence and depression occurs in clinical samples, there is far less agreement concerning the nature or direction (primary or secondary) of this relationship. This distinction is necessary in determining whether alcohol misuse and depression are different symptomatic expressions of a common dysfunctional neurobiological substrate or whether one condition induces the other. In contrast, alcohol abuse is also frequently comorbid with bipolar disorder and posttraumatic stress disorder, but in these cases it is usually temporally secondary.

Nicotine

In the case of nicotine, investigation of a subset of NCS participants found that psychiatric disorders predicted an increased risk for the first onset of daily smoking and subsequent nicotine dependence. Most notable are people with schizophrenia, who have smoking rates of between 70 and 90% (compared to approximately 25% for the general population), resulting in excess morbidity and mortality in this group. As well, nicotine dependence is twice as prevalent in patients with mood, anxiety, or personality disorders than in the general population. The reasons for this increased rate of use include self-medication to ameliorate the symptoms of the disorder or the side-effects of treatment.

Conversely, it has also been proposed that daily smoking is a causal factor in panic disorder and agoraphobia, conditions that for some individuals may be relieved by smoking cessation. Of interest also are data on twins centered on the familial aggregation of smoking and depression, indicating common or shared genes as a source of this association. Defining the interaction between genes and environment in such comorbidity is important in understanding why increased risk for substance use occurs.

Illicit Drugs

The risk relationship between illicit substance use and other psychiatric disorder appears to be reciprocal, with one predicting the increased likelihood of the other. Moreover, approximately one in five people report the use of more than one illicit drug. The substances most frequently misused include cannabis,

amphetamines, opioids (heroin), cocaine, hallucinogens, ecstasy or MDMA (N-methyl-3,4-methylenedioxy-methamphetamine), and benzodiazepines (nonprescribed use). As may be anticipated, individuals with multiple dependencies experience the highest rates of psychiatric comorbidity. Most psychiatric illnesses including psychotic, mood, anxiety, or alcohol-use disorders are often comorbid with illicit SUDs. In such psychiatric cohorts, gender differences in drug use are commonly substance-type-specific. For example, men are twice more likely than women to meet the criteria for cannabis abuse or dependence; however, in cocaine and opioid abusers, the numbers are generally similar between the sexes. It is also prudent to highlight that differences in the availability of illicit drugs in the study location may explain the data gathered. Thus, whereas cocaine is the illicit drug most commonly used by incarcerated women in the United States, cannabis, opioids, and benzodiazepines were most frequently used in an Australian cohort.

Etiological Theories

Each class of abused drugs is chemically diverse and produces effects through actions at different specific cellular and molecular targets within the brain; nevertheless, the pathways underlying reward and dependence are thought to be similar. The common mode of action involves all drugs of abuse releasing dopamine, either directly or indirectly, within the shell of the nucleus accumbens. This dopamine is released from neurons that originate in the ventral tegmental area (VTA) and terminate in the nucleus accumbens, amygdala, the bed nucleus of the stria terminalis, and other regions and are termed the mesolimbic dopamine projection. This is thought to be the path for all natural rewards such as food and sex and also for other nondrug rewards such as gambling. However, repeated drug use that results in drug dependence is more complex than simple changes in extracellular dopamine or receptor sensitivity. Drug dependence comprises a number of aspects including the need for the drug, the motivation to use it, the reward or pleasurable aspect of the use, and the relief from withdrawal symptoms. The brain regions and neurochemical pathways underpinning these distinct behavioral processes differ and are not fully elucidated, although they are considered to be similar between drugs of abuse. How these pathways are involved with the manifestation of other psychiatric disorders and how the pathologies of both sets of disorders may interact and be modulated by stress are poorly understood. Hence, although there is convincing epidemiological evidence linking psychiatric disorder

and SUDs and stress, direct biological evidence explaining this association is limited. Several competing theories have been proposed to explain this high co-occurrence.

Common Factor Models

Common factor models posit that comorbidity is the result of shared vulnerability to both disorders. Specific factors can independently increase the risk of developing both disorders and thus the increased comorbidity is explained. For example, common genetic predisposition may underlie both the index and the comorbid condition. Other possible common factors include social class of rearing, family disruption, cognitive functioning, and exposure to an environmental toxin (e.g., lead).

Genetics There is clear evidence that genetic factors play a role in both most major psychiatric disorders, including schizophrenia, bipolar disorder, and major depression, and in SUDs. The question is whether genetics contributes to comorbidity. Studies have shown that comorbid patients are more likely to have relatives with a SUD than patients without a dual diagnosis; however, this does not imply linked genetic factors. An alternative question is whether genetic vulnerability to one disorder increases the risk of exposure to the other disorder. Data addressing this point indicate that the genetic risk of schizophrenia is not associated with an increased risk of SUD in relatives, or vice versa. Such findings suggest that shared genetic factors do not explain the increased rates of comorbid substance use in schizophrenia. This conclusion is also supported by twin studies on the heritability of schizophrenia and alcoholism, in which the rates of the disorders between monozygotic and dizygotic twins were compared and no correlation was found. A 2003 large multivariate modeling study using same-sex twins demonstrated that common genetic factors for SUDs loaded with adult antisocial behavior and conduct disorder but not with internalizing disorders such as major depression and anxiety disorders. These data contribute to dispelling notions of a common shared genetic vulnerability but not of disorder-specific interactions. Consequently, although there may be some genetic contribution to comorbidity, the problem remains of identifying which factors are inherited and how they interact with other personal traits and facets of the environment to elevate risk.

Secondary Substance Disorder Models

Several models postulate that psychiatric illness increases the vulnerability of a patient to developing a SUD. These models are broadly characterized into

two types: the self-medication model and the supersensitivity model.

Self-Medication Model Self-medication denotes that individuals use specific substances to attenuate adverse states caused either by their psychiatric disorder or by its treatment. The underlying assumption is that substances are used in a selective manner based on their distinct pharmacological effects. Examples of symptom alleviation include the use of nicotine by people with schizophrenia to normalize deficits in sensory processing (attention) or the use of stimulant drugs (amphetamines and cocaine) by depressed patients to counter anergic symptoms (lack of energy and amotivation). An example of substance use mitigating the side-effects of psychotropic medications is nicotine relieving the extrapyramidal motor and dysphoric side-effects induced by antipsychotic medication; it is proposed that it releases dopamine to ameliorate the dopamine D2 receptor blockade induced by the medication. As intuitively appealing as the self-medication hypothesis is, the evidence is not supportive. First, much substance use, especially cigarette smoking, precedes the first symptoms of the psychiatric disorder, let alone the first treatment. Second, the factors most consistently associated with substance use in psychiatric patients, such as availability, cost, compliance with the peer group, facilitation of social interaction, intoxication, and relaxation, are the same as that observed in the general community. Similarly, patients seldom report self-medication as a reason for substance use. Finally, the choice of substance does not appear to be related to the psychiatric diagnosis or type or severity of symptoms.

The Supersensitivity Model This model contends that a combination of genetic and early environmental (pre- or postnatal) events interact with an environmental stressor to precipitate the onset or relapse of a psychiatric disorder in a vulnerable individual, where vulnerability is defined as a compromised biological sensitivity to stress. Therefore, whereas psychotropic medications can be protective or decrease vulnerability, substance abuse may increase it. This sensitivity may then make psychiatric patients more likely to experience negative consequences from using even small amounts of the substance. The assertion is that these negative outcomes of substance use, rather than the use itself, is what differentiates comorbid patients from the general population. Hence, given a similar volume of use, a greater proportion of people with psychiatric disorders will present with problematic use. Various observations provide support for this model, including the lesser amounts of substance used by comorbid patients, induction of clinical

symptoms by low-dose drug (amphetamine) challenge tests, and negative effects such as relapse following the administration of small quantities of the substance. Similarly, a longitudinal examination of the course of drinking alcohol in a psychiatric cohort found that fewer than 5% were able to sustain symptom-free drinking over time without negative consequences, compared to approximately 50% within the general population.

Secondary Psychiatric Disorder Model

This model posits that the SUD induces the psychiatric disorder, based on observations of the psychotogenic effects of drugs such as stimulants (amphetamines and cocaine), hallucinogens (lysergic acid diethylamide), and cannabis and the depressive effects of alcohol. However, the complex interaction of neurobiological and psychosocial factors that underlie each disorder often makes the assignment of causality in this direction difficult.

Comorbidity between schizophrenia and cannabis use illustrates this point. Cannabis may induce a transient psychotic state characterized by hallucinations and agitation that may be difficult to differentiate from a primary psychotic disorder. Further, cannabis use commonly precedes the onset of schizophrenia. Trying to determine the issue of causality, however, is hard given that the available evidence is largely based on epidemiological studies. A 2002 meta-analysis concluded that cannabis use accounted for approximately 8% of the attributable risk for developing schizophrenia. This may account for the anecdotal clinical observations of cannabis causing schizophrenia and the conflicting prevalence data that frequently show no relation between the two disorders.

With respect to alcohol use and depression, the notion is that alcohol increases the risk and severity of depression, although no causal association has been established. This is complicated by the general observation that alcohol abuse and dependence develops after the onset of bipolar disorder, again emphasizing the need to carefully differentiate particular disorders and their comorbidity.

Bidirectional Models

Bidirectional models suggest interactional effects between psychiatric and SUDs that account for the high co-occurrence rates. For example, a SUD could trigger a psychiatric illness in a vulnerable individual, which is maintained by continued substance use due to cognitive factors, social conditioning, beliefs, and motivations. Despite evidence that substance misuse worsens the course of psychiatric illness, these postulates, although highly plausible, remain largely theoretical and untested.

Comorbidity and Stress

An extension of causal explanations for the co-occurrence of psychiatric and SUDs incorporates stress as central to the genesis and perpetuation of the comorbid state. It should be noted that the role of stress has already been well established independently in both SUDs and other psychiatric disorders. This is based on increasing evidence that these disorders are associated with maladaptive neurobiological changes in brain stress circuits that principally comprise the hypothalamic-pituitary-adrenal (HPA) axis, corticotropin releasing hormone (CRH), and noradrenergic systems. The primary stress mediators of this endocrine system include the glucocorticoids (adrenal steroids such as cortisol) and catecholamines (dopamine, norepinephrine, and epinephrine), which in the short term are vital for the adaptation and maintenance of homeostasis but which can act detrimentally with repeated long-term release. As previously mentioned, chronic drug use is linked with neuroadaptations in the brain reward pathways, predominantly involving mesolimbic dopamine projections. One possible mechanism of interaction could be that stress activation of the HPA axis causes the release of glucocorticoids that interact with mesolimbic dopamine release and stimulate neuronal pathways implicated in substance misuse. Neuroadaptations in stress and reward circuits may, accordingly, underlie the adverse states often associated with psychiatric disorders and SUDs. It is feasible therefore that common mechanisms influencing stress, motivation, and behavior may contribute to comorbidity.

Data indicate that stress plays a role in the development and relapse of comorbid disorders. For instance, high levels of exposure to adversity or stressful events have been causally related to the onset of depressive and anxiety disorders. Similarly, stressors may facilitate substance misuse by increasing the reinforcing efficacy of substances that ameliorate the anxiety and dysphoric symptoms induced by stress. Further support is obtained from animal studies in which stress can induce drug self-administration, increase the sensitivity to the reinforcing effects of drugs, and precipitate the reinstatement or relapse of substance use even after prolonged periods of withdrawal. Hence, from a theoretical perspective, stress has been proposed as a factor that links psychiatric disorders and SUDs. This model postulates that a chronic distress state due to repeated stress exposure underlies the severity of psychiatric symptoms and substance use. This adverse state is then associated with maladaptive responses such as drug use in order to maintain homeostasis. Maladaptive responses may, in turn, alter HPA or CRH circuits and various neurotransmitter systems to induce substance

craving and poor behavioral or coping strategies, causing neuroadaptations in the brain stress and reward pathways. Increased drug use to levels characteristic of dependence leads to further changes in these circuits. Such alterations thereby promote the susceptibility to recurrent stress exposure in comorbid individuals. Supporting this paradigm is the notion that various genetic and environmental vulnerability factors (such as family history and social influences, individual differences in responsiveness to substances, specific personality traits, early life trauma, and poor cognitive functioning) aid development of distress states.

Major Depression, Substance Use Disorders, and Stress

A number of the issues discussed here may be usefully illustrated using the relationship among major depression (MD), SUDs, and stress. As previously noted, the high rate of MD in people with a primary SUD and vice versa underscores the increased risk of an individual with one disorder developing the other. Furthermore, there is considerable evidence relating stressors to the onset, perpetuation, and relapse to either MD or SUD. Hence, it may be that life stressors predispose to each disorder independently, that the stress in predisposing the individual to one disorder renders him or her vulnerable to the development of the other, or that underlying factors such as genes or early environment predispose the individual to experiencing stressors, MD, and SUDs. In parallel with understanding these interactions among MD, SUDs, and life stressors from a psychosocial epidemiological perspective, the involvement of CRH and the HPA axis in both MD and SUD suggests shared neural substrates.

Unraveling these associations is only just beginning; however, there is some clinical, biochemical, and neuroimaging evidence to this end. Clinically, MD and substance withdrawal share similarities, including dysphoria or lowered mood, irritability, anxiety, sleep and appetite changes, and impaired concentration. This is especially so for alcohol withdrawal, in which a depressive phase indistinguishable from MD is present initially in up to 80% of patients but commonly remits without antidepressant treatment.

In functional imaging studies using positron emission tomography or functional magnetic resonance imaging of MD reduced frontal metabolism, anterior cingulate hypoactivity and amygdala hyperactivity indicate altered frontolimbic functioning. Similarly, in people with SUDs, decreased frontal and anterior cingulate activity has been described, in particular in distressed cocaine-dependent subjects and methamphetamine abusers with mood and anxiety symptoms.

This group of methamphetamine abusers also demonstrated amygdala hyperactivity, a finding noted in abstaining cocaine-dependent people with cravings induced by image cues. Although these data are not definitive, they indicate that MD and SUDs share common neural regions of dysregulation that are associated with negative affect and stress-related drug seeking.

In acute withdrawal from nicotine and cocaine, both the distress and depressive symptoms positively correlate with changes in CRH and HPA axis responses. Blunted ACTH and cortisol responses to CRH have also been described in people with SUDs, both with and without depressive symptoms. Consistent with this, individuals abstaining from nicotine, alcohol, or multiple substances demonstrated blunted cortisol responses to psychological stressors; D-fenfluramine induced a similar response in abstaining heroin users. These attenuated responses may indicate overactivity of the HPA axis and are commonly seen in MD. The role of this axis is supported by the observations in animal studies that the stress of repeated foot shocks precipitated a relapse to drug use that was prevented by CRH antagonists. In addition, the extrahypothalamic role of CRH in the bed nucleus of the stria terminalis and amygdala is important in mediating the effects of external stressors on relapses to drug use in animal models. Thus, overall increased CRH-related function has been implicated for substance withdrawal, at least for psychostimulants, opioids, ethanol, nicotine, and benzodiazepines. This same change is described in MD with increased CRH levels in the cerebrospinal fluid of depressed subjects and a decrease in CRH levels with antidepressant or electroconvulsive treatment. Hence, it may be that stress as reflected through the perturbation of CRH has a common effect on MD and substance withdrawal.

The most commonly noted neurochemical system changes in MD are the monoamines, especially serotonin and norepinephrine (NE), and CRH and the HPA axis. Some evidence supports a role for dopamine dysfunction; however, therapeutic strategies augmenting dopamine neurotransmission are of equivocal benefit. In contrast, for SUDs dopamine release in the nucleus accumbens is the central mechanism of reward and motivation for use and as previously noted CRH-HPA axis dysregulation appears during withdrawal. Therefore the neuroimaging findings of a shared frontolimbic circuit dysfunction in MD and SUDs probably involve other linking neural systems. Although speculative, one possibility is through CRH-HPA axis and NE, where either peripheral glucocorticoids cross the blood-brain barrier or NE from the locus coeruleus bind to its receptors in the nucleus

accumbens and ventral tegmental area, enhancing DA release within the nucleus accumbens similar to drugs of abuse. Thus, a well-described finding in MD of altered CRH-HPA axis and NE activity can influence the central pathway involved in SUDs. This probably oversimplified schema suggests that a primary MD increases vulnerability to a subsequent SUD and that substance use may be compensatory in reestablishing homeostasis in a deficient reward-motivation pathway. Although it is problematic to extrapolate from clinical observations to neural mechanisms, this proposal is consistent with a much greater decrease in cocaine use in depressed cocaine users compared to nondepressed users when both were treated with antidepressants. Similar but more modest effects have been noted for both alcohol and nicotine users. Also, MD is known to sensitize smokers to stress, which increases the motivation for smoking. Moreover, for abstaining smokers with a psychiatric disorder, depression often accompanies nicotine withdrawal, with relief from these symptoms prompting a relapse. Smokers therefore anticipate that nicotine will provide partial relief from stress and depression, as it does from the symptoms of withdrawal. In support of this premise is the finding that stress and nicotine both induce synaptogenesis (synapse formation) in the VTA. Furthermore, increase in dopamine release caused by nicotine is suggested to improve anhedonia (loss of pleasure), often associated with depressive illness.

Conclusion

This article describes the high rate of comorbidity between SUDs and other psychiatric disorders, briefly outlines competing hypotheses to explain this observation, proposes how stress may contribute to this, and illustrates this with reference to major depression. However, despite the strong epidemiological evidence of a high rate of comorbidity between SUDs and other psychiatric disorders that is exacerbated by stress, the divergent pathologies of major psychiatric disorders and the limited understanding of the neuroadaptations involved in SUDs suggest

that this interaction differs between the disorders. Moreover, although there is limited evidence to support the self-medication hypotheses, alternative explanatory hypotheses remain plausible. Thus, untangling the interaction of stress-related factors in the neurobiological findings in these disorders and their effects on the brain changes from substance dependence will be essential in determining the correct hypothesis of comorbidity. The result of this endeavor could have profound effects on the prevention and treatment of SUD and other psychiatric disorder comorbidity.

Stress Responses Defined

Stress Responses in Invertebrates

Stress Responses in Vertebrates

Impact of Stress on the Regulation of Energy Metabolism

Glossary

<i>Cyclostome</i>	A member of the order Cyclostomata (class Agnatha): hagfish and lampreys. These primitive vertebrates have relatively rudimentary endocrine and nervous systems that are thought to represent evolutionarily early examples of these functions.
<i>Cytokine</i>	Regulatory proteins secreted by the white blood cells and a variety of other cells in the body. Cytokines can regulate cells of the immune system and modulate immune responses, but act in a relatively local manner.
<i>Elasmobranch</i>	Cartilaginous fish (e.g., sharks, skates, and rays).
<i>Fenestrated capillary</i>	A specialized capillary that has transcellular circular openings in the endothelial walls allowing the passage of large molecules in or out of the capillary. They are particularly prevalent in regions where secretory products are released into the vasculature.
<i>Mesoderm</i>	One of the three principal layers of the mammalian embryo from which the vascular tissues are derived.
<i>Tetrapod</i>	A four-limbed vertebrate.

Stress Responses Defined

Using the simplest and most wide-ranging definition, a stressor can be thought of as any alteration in the animal's environment (internal or external) requiring a response that, if not invoked, could develop into a threat to survival. In some instances, the disturbance might only require a simple avoidance reflex that moves the animal away from an external threat; in others it might invoke an internally directed motor response nullifying a homeostatic disturbance.

Considered in this broader manner, stress responses are fundamental characteristics displayed by all living organisms. Protozoans display an avoidance reaction to a detrimental change in the local environment, for example, increased CO₂ concentrations in the water; more complex multicellular organisms such as coelenterates and platyhelminths have sensory-motor networks that allow them to make the appropriate distinction between a threat and a meal. All animals use some sort of avoidance (generally reflexive) reaction that can be considered a stress response to an aversive presence in the environment. However, more complex invertebrates and all vertebrates have also evolved sets of physiological responses that provide the organism with the ability to adapt their metabolic and immune systems to deal with the consequences of stress. In these animals, physiological and neural systems involving learning and memory also provide organisms with anticipatory features allowing them to generate conditioned or habituated responses as well as the capability of dealing with the more extended consequences of stress.

Stress Responses in Invertebrates

Stress responses in invertebrates can be divided into two broad categories: (1) those concerned with abrogating the stressor and (2) adaptive changes invoked to deal with the metabolic consequences of the stressor. In invertebrates, the nervous system generally deals with the first, whereas cellular interactions of a chemical nature (endocrine and immune) generally deal with the second.

Neural

For avoidance responses, sessile invertebrates generally confront a threat by retracting vulnerable body parts into a protective shell or the environmental surroundings, whereas more mobile species have the ability to move away from the threat as fast as possible. In most metazoans, the effector of these responses is the nervous system. Simple invertebrates such as coelenterates have avoidance reactions that may involve little more than invoking the stimulus-response properties of their nerve nets. In more complex invertebrates, these avoidance reactions are neurophysiologically quite complex and involve the regulation of specific neural networks by sensory inputs (e.g., air currents). These networks coordinate the very rapid muscle contraction required for fleeing (e.g., jumping, flying, turning, or running). These responses

appear to involve populations of giant interneurons found in the abdominal ganglia that may, because of their fast conduction velocities, bring about the very rapid stimulus–response interactions required for these behaviors. However, the detailed role of these neurons and the wider functioning of this circuitry remains unclear. Although all of these avoidance responses have the characteristics of a reflex, studies from species such as *Aplysia* have shown that contributions from learning and memory mechanisms cannot be overlooked.

Endocrine

Arthropods use hormones to regulate their metabolism in a way that is beneficial during periods of stress. In a manner somewhat analogous to the secretions of the vertebrate chromaffin cell–adrenal medulla system, some insects (e.g., locusts and cockroaches) produce adipokinetic hormones (AKH) in the gland cells of the corpora cardiaca. These hormones increase the heart rate and the carbohydrate and protein metabolism. They also produce hyperglycemia through the breakdown of glycogen to trehalose in the fat bodies and muscles and its facilitated transport into the hemolymph. Starvation, increased activity, and stress all elevate the secretion rate of these hormones.

Complex invertebrates such as annelids, insects, and mollusks possess quite sophisticated immune functions that use interleukin-like signaling molecules and cytotoxic activities derived from natural killer cells. These systems are activated by stressors. Some invertebrates also synthesize corticotropin releasing hormone (CRH) and proopiomelanocortin-(POMC-) derived peptides that are related to their vertebrate homologs. In molluscs, CRH and adrenocorticotrophic hormone (ACTH) are capable of releasing biogenic amines from hemocytes (cells that appear to have both endocrine and immune functions), and at least some of the cells that are capable of phagocytosis also exhibit ACTH immunoreactivity. ACTH-like molecules have even been identified in some protozoans, suggesting their great phylogenetic antiquity. Indeed, the existence of those endocrine signals capable of regulating carbohydrate metabolism and immune responses – properties required to generate adaptive responses to stressors – appear to have developed very early in evolution.

Stress Responses in Vertebrates

Not surprisingly, stress responses in vertebrates have more components, variety, and complexity than those found in invertebrates. Although some vertebrate stress responses are similar in principle to those exhibited by invertebrates (e.g., avoidance, endocrine

secretions that increase energy substrate availability, and adaptations that restrict reproduction), because of their more complex central nervous systems, vertebrates possess a greater flexibility and adaptative capability.

Comparative Anatomy

The general organization of those parts of the neural and endocrine systems involved with mediating stress responses are remarkably well conserved across all vertebrate classes.

The neurohypophysis The neurohypophysis comprises the median eminence of the tuber cinereum, the infundibular stem, and the neural lobe of the pituitary gland. The median eminence and the neural lobe both contain terminals of neuroendocrine motor neurons. However, neurons that regulate ACTH secretion terminate in the median eminence. With appropriate increases in firing rate, they release releasing factors (CRH and, in some mammals, vasopressin) into the hypophyseal portal blood. The neurons that release oxytocin and vasopressin/vasotocin into the general circulation terminate on fenestrated capillaries in the neural lobe. The neural lobe appears to be better developed in tetrapods than in fish, and this may be related to the larger amount of stored hormone required for the increased hydrostatic stresses of terrestrial existence. With a few exceptions (e.g., in cyclostomes, the neurohypophysis is quite poorly developed), the generalized organization of the neurohypophysis is retained across the vertebrate spectrum.

Corticotropes The anterior pituitary of all vertebrates contains cells that synthesize ACTH. In evolutionarily older species (e.g., reptiles and elasmobranchs) there is less intermingling of cell types within the anterior pituitary than is found in more recently evolved species. POMC is cleaved to produce ACTH in the anterior pituitary corticotropes in all vertebrate classes, in which it acts to increase glucocorticoid secretion. Negative glucocorticoid feedback signals also appears to operate in all vertebrate classes examined.

Catecholaminergic and corticosteroidogenic tissues The analog of the adrenal gland is critical to the stress response of all vertebrates. In mammals, it is called the adrenal (or in older literature, the suprarenal) gland because of its position close to the kidneys. In mammals, the adrenal gland has a characteristic cortical and medullary structure – the medulla is neural in origin and synthesizes catecholamines for release into the bloodstream on sympathetic stimulation; the

cortex is mesodermal in origin and is the site of glucocorticoid and mineralocorticoid synthesis. Although cells performing these functions are found in all vertebrates, the way they are arranged and their anatomical association vary from class to class. In amphibians, reptiles, and fish, this tissue is found between the renal tissue and is sometimes called the interrenal gland.

All vertebrates possess tissue that can secrete catecholamines into the bloodstream during stress. Catecholamines (usually adrenaline and noradrenaline) universally increase cardiovascular muscle tone, increase heart rate, and can rapidly mobilize fat and carbohydrate stores. There has been a trend during evolution toward a close relationship between catecholamine-synthesizing and steroidogenic tissue. Thus, in the cyclostomes and some elasmobranchs, chromaffin cells are widely scattered along large veins and the dorsal body wall, but steroidogenic tissue has been more difficult to identify. In many vertebrate classes, catecholaminergic tissue is interspersed with steroidogenic tissue. In mammals, however, chromaffin cells are aggregated in the adrenal medulla and are separate from the steroid-synthesizing cells in the adrenal cortex, although a close functional relationship does exist.

Sympathetic branch of the autonomic nervous system Sympathetic motor activation plays an important role in the stress responses in virtually all vertebrates. However, it is poorly developed in cyclostomes, in which there are no sympathetic chains and relatively little sympathetic innervation of the viscera. In teleost fish, catecholamine secretion is regulated by preganglionic sympathetic activation. However, other regulators such as glucocorticoids can also play an important role. It is possible that the chromaffin cell system first evolved to function as the principal regulator of the cardiovascular and energy metabolism under all conditions, not just stress. But as the sympathetic innervation of the cardiovascular system became more sophisticated and was able to regulate visceral organ function under basal conditions, the actions of the chromaffin system during stress became the more important function.

Juxtaglomerular apparatus Renin and the cells that contain juxtaglomerular granules are found in all vertebrates other than cyclostomes. In more recently evolved vertebrates, these are aggregated in a specific juxtaglomerular apparatus (juxtaglomerular cells and the macula densa), whereas in others only juxtaglomerular cells are seen. In teleost and more primitive fish species, these are often quite distal from the glomerular apparatus.

Comparative Physiology

Vertebrates invoke sets of stress responses that target three critical physiological systems – those involved with fluid balance, energy metabolism, and tissue damage and immune function. Each set has specific neural and endocrine components.

Impact of stress on the regulation of fluid balance

Protecting the fluid compartments of the body is a prime physiological concern, and the physiological systems that contribute to this function are usually activated during stress. Two sets of hormones have evolved to regulate fluid balance; the renin–angiotensin system protects the extracellular fluid compartment, whereas the posterior pituitary lobe hormones regulate the intracellular fluid compartment. In addition, autonomic reflexes are available to regulate cardiovascular and hemodynamic function through the control of vascular tone. Both systems are stimulated by stress.

Renin–angiotensin system The renin–angiotensin system targets vascular smooth muscle, mineralocorticoid-synthesizing tissue in the adrenal cortex, and some circumventricular organs in the brain. Renin is present in all jawed vertebrates, but is absent in the cyclostomes. Its original function may have been to increase blood pressure through vasoconstriction, with its dipsogenic and other effects (e.g., increased release of mineralocorticoids) appearing later.

Vasotocin/vasopressin Maintaining body fluid composition between narrow limits is a requirement for survival for all organisms. This becomes absolute in animals that live in environments of varying temperature or water availability and in animals that move from one major environment to another. Any variation that challenges fluid balance constitutes a stressor that needs to be regulated. The vertebrate brain has evolved a very simple reflex loop to help with this regulation, and such a function has remained reasonably unchanged for the 500 million years since the evolution of the cyclostomes. It involves direct projections from the osmoreceptors to the neuroendocrine neurons that synthesize vasopressin (in mammals) or vasotocin (in birds, reptiles, and most amphibians and fish, including cyclostomes). In this manner, one of the simplest and phylogenetically oldest vertebrate neuroendocrine stress response is probably the reflex release into the circulation of vasopressin/vasotocin that occurs as plasma osmolality increases. The original function of vasotocin (which is still its primary action in some amphibians) may have been a V1 receptor-mediated vasoconstrictive effect that reduces blood flow to the kidney and thereby fluid loss. (In this

respect, vasotocin is a more potent vasoconstrictor than its evolutionary descendant, vasopressin). However, during evolution a V2-mediated action on kidney tubules became the predominant action.

Impact of Stress on the Regulation of Energy Metabolism

Glucocorticoids

The stress-induced release of glucocorticoids is found widely throughout vertebrate classes, in which they act to promote gluconeogenesis. Stress-induced hyperglycemia reportedly occurs in all classes of vertebrates that have been investigated, from cyclostomes to mammals, although the contribution of glucocorticoids to this effect is far from clear in more simple vertebrates. It is worth considering that, in many respects, the hypothalamic-pituitary-adrenal (HPA) motor response to stress is a more proactive than a reactive event. Although ACTH and corticosterone secretion are obviously triggered by the stressor, they are not the motor responses that act to remove the immediate consequences of the stress, as occurs with, for example, adrenaline's actions to generate hypoglycemia. The actions of elevated plasma corticosterone levels (mediated in part by interactions with leptin, insulin, and the thyroid hormones) anticipate the possibility that the stressor will lead to a debilitating sequence of events, particularly the catabolic effects of negative energy balance. In those vertebrate classes that have been studied, the principal function of corticosteroids is on the intermediate metabolism, particularly in stimulating proteolysis and then gluconeogenesis.

Catecholamines of chromaffin cell origin

Increased circulating catecholamines lead to hyperglycemia in all vertebrates examined, although noradrenaline and adrenaline show differences in efficacy across different classes. Also, the tissue that is targeted varies; in mammals both muscle and liver are responsive to adrenaline, whereas only liver glycogen is mobilized in cyclostomes. Stress will increase plasma catecholamines in teleost fish and elasmobranchs.

Inhibition of reproduction

A variety of stressors inhibits reproductive function in most vertebrates. The simplest of these is the negative

energy balance resulting from food restriction or starvation. Here a mechanism (possibly involving elevated neuropeptide Y synthesis in the hypothalamic arcuate nucleus) leads to the inhibition of reproductive function, ensuring that limited energy supplies are not used to raise offspring in adverse conditions. Related stressors such as social crowding may also restrict reproductive capacity for the same reason, although the neural mechanism responsible for this effect is unclear.

Impact of stress on the regulation of immune function

Immune activation and the consequent increases in circulating interleukins that occur during some stressors provide a marked stimulus to the vertebrate HPA axis. In mammals, this elevates CRH release into the portal vasculature and, hence, ACTH release. Increased glucocorticoid release in response to cytokines has been noted in all the mammals, reptiles, birds, and amphibians that have been investigated. However, it should be noted that in nonmammalian classes, data are very scanty. In turn, corticosteroids have a suppressive effect on immune function. During acute stress, this operates as a dampening effect to restrain any adverse effect of immune stimulation, but in chronic stress this can have a deleterious effect leading to increased infections and mortality. These types of effect have been seen in a wide variety of vertebrates.

 Concentration Camp Survivors and the Global War On
 Terrorism
 Summary

Glossary

<i>Concentration camp</i>	A camp where prisoners of war, enemies, aliens, or political prisoners are confined. The term implies that physical mistreatment, torture, indiscriminate murder, and genocide can occur.
<i>Depression</i>	A specific psychiatric disorder consisting of lowered mood and symptoms, such as decreased interest in most activity, loss of appetite and weight, poor sleep, fatigue, feelings of worthlessness, poor concentration, and recurrent thoughts of death.
<i>Holocaust</i>	The systematic destruction of over six million European Jews by the Nazis before and during World War II.
<i>Posttraumatic stress disorder (PTSD)</i>	A specific psychiatric disorder following psychological trauma with symptoms of reexperiencing, such as nightmares and flashback; avoidance behavior, such as attempts to avoid thoughts and memories of the events; and hyperarousal symptoms, such as irritability, startle response, and difficulty sleeping.

History of Concentration Camp Syndrome

There is probably no more stressful environment than that of a concentration camp, where people are detained for their combatant or alien status, their political views, or even their ethnicity. The purposes of such camps are often to control, punish, or kill its occupants. Words cannot describe the worse conditions, but crowded living, forced labor, starvation diets, lack of medical treatment, torture, and random or systematic murder are usual. Understandably, the physical and mental effects of the survivors are severe.

A constant and persistent group of symptoms were found among survivors of Nazi concentration camps, which then became known as the concentration camp syndrome. This consists of marked anxiety, motor restlessness, hyperapprehensiveness (startle reactions), sleep disturbance, nightmares, difficulty in concentration, obsessive rumination about the traumatic events, depression, and survivor guilt. Some symptoms seem to represent a form of brain damage, and early researchers found that beatings, malnutrition, and disease were the cause of this disorder; however, it eventually became apparent that the severe psychological trauma itself was the cause of this disorder, and it could occur in previously emotionally healthy persons. Several psychiatrists describing the survivors reported that none have escaped the effects; although the effects may be a subtle personality change, such as apathy, seclusiveness, suspiciousness, hostility, and mistrust. The concentration camp syndrome never became a formal American Psychiatric Association diagnosis, but it had much similarity with diagnosis of posttraumatic stress disorder (PTSD), which was recognized in 1980.

Nazi Concentration Camp Survivors

Background

Six million people (mostly Jews) were killed in Nazi concentration camps. Some camps (Treblinka, Auschwitz-Birkenau, Dachau, Chelmno, Sobibor, Belzek, and Majdanek) were for exterminations. Others had less systematic murder, but were characterized by starvation, forced labor, torture, endemic disease, beatings, inadequate clothing, death marches, and a lack of proper medical facilities. While living with constant threats to their lives, camp prisoners were subjected to medical experimentation, gross humiliation, and separation from family and were forced to witness severe cruelty to others. They were defenseless without privacy or any means of protection. Further details may be obtained from *A Teacher's guide to the Holocaust*. The experience lasted 4 years before liberation came at the end of World War II. Much information up to now has been accumulated on the effects of the survivors.

Physical Effects

In a study of physical sequelae of the Holocaust in Norway, survivors had a higher mortality, more frequent hospitalizations, and higher incidents of sick periods. Physical symptoms, such as headaches, persistent dizziness, and gastrointestinal complaints, which can persist 50 years later, were common.

However, most survivors have reported symptoms with a psychogenic component. Few differences have been found for such diagnostic disorders as arthritis, cancer, and Parkinson's disease.

Psychiatric Effects

There have been many community-based, large-scale studies on the Holocaust survivors, some 40 years after the events. Unlike the previous studies on patients seeking clinical help, these have consistently shown more distress in symptoms and lower mood in survivors than in controls.

In one study, 43% of survivors had symptoms compared to 28% of controls. However, there was considerable overlap and some survivors had fewer symptoms than controls. In one study, 40 years after the Holocaust, 46.8% of survivors met the diagnosis of PTSD. Although the trauma experiences of the Holocaust victims were universally severe, some evidence that the more severe trauma, i.e., surviving a death camp setting or being incarcerated longer, had more symptoms. Greater psychological problems were seen in those who experienced the Holocaust as children and showed more PTSD symptoms. Female victims report more distress than males. The Nazi concentration camp victims tended to remain vulnerable to reactivation of symptoms during stress, whether this redevelopment of PTSD symptoms occurred in actual trauma, such as scud missile attacks during the Gulf War, or a perceived threat, such as a sense of increased anti-Semitism. The Nazi concentration camps were so horrible and the evil committed was so beyond comprehension that clinical terms may not do justice to the existential and theological despair of mankind's inhumanity.

Prisoners of War Concentration Camp Survivors

Background

Wars and upheaval in this century have led to thousands experiencing captivity by the enemy often with malnutrition, overcrowding, torture, poor diet, inadequate shelter, and terrorizing executions. The long-term effects have been reported in survivors in the United States, Australia, Israel, Canada, The Netherlands, United Kingdom, and, more recently, Bosnia Herzegovina.

Physical Effects

American prisoners of war (POWs) from Japan had excess mortality from accidents and tuberculosis. POWs from the Korean War had increased cognitive

deficits that were related to the amount of captivity and weight loss.

Psychiatric Effects

Follow-up studies of the POWs demonstrated a uniformly high rate of persistent and debilitating psychiatric disorders. High rates of psychiatric hospitalizations for neurosis were found in POWs from World War II of Germany and Japan. In another study, high rates of anxiety reaction, alcoholism, and even schizophrenia have been found with greater occurrence in the POWs held by Japan, which inflicted more cruelty on the prisoners. More than 40–50 years after World War II and the Korean War, over half had at sometime a diagnosis of PTSD. The severely traumatized group of POWs held by Japan had a PTSD lifetime prevalence of 84% and a current diagnosis of 58%. PTSD also greatly increases the risk of other disorders, including depression and alcoholism. From a series of studies, we know that the POW concentration camp experience has severe and persistent effects, with up to 50% having PTSD, depression, and alcohol abuse. Many studies found that few survivors actively sought medical treatment and were suffering quite privately.

Cambodian Pol Pot Concentration Camp Survivors

Background

One of the most recent and best-studied concentration camp experiences was that afflicted on the Cambodian people by the radical Marxist Pol Pot regime between 1975 and 1979. During this brutal time, millions of people were rounded up and placed in isolated camps with forced labor, no medical facilities, starvation diets, indiscriminate beatings, and murders, often with family members watching helplessly. One-quarter to one-third of Cambodia's seven million people died during this time. Many survivors went to Thailand as refugees and were later given asylum in Western countries.

Physical Effects

Even after they have improved physically from acute effects, many Cambodian refugees continue to report somatic complaints; 15–20% reported much health impairment. A very high percentage of Cambodian clinic patients (59% of males and 49% of females) have documented hypertension. Incidence of type 2 diabetes is about the same as the population in the United States (about 13.5%) but its prevalence is higher in young people than in the United States. It is difficult to know if these effects are due to refugee

status or dietary in addition to the probable long-term effects of trauma.

Psychiatric Effects

The first studies on Cambodian concentration camp survivors found that the symptoms of nightmares, startle reaction, intrusive memories of events, a strong tendency to avoid thinking about this, and marked concentration problems persisted. In addition to these symptoms of PTSD, most have major depressive symptoms. In a community study (nonpatients), 50% of Cambodians were found to have PTSD and 50% also had depression. The depression symptoms increased over time, unlike the PTSD symptoms, which tend to wax and wane, but continue to affect about 50% of Cambodians even 12 years later. An important finding was the marked sensitivity to stress. Cambodians who witnessed accidents, underwent surgery, or even saw violence on television, such as viewing the destruction of the twin towers on 11 September 2001, had acute PTSD symptoms involving the trauma in Cambodia. Interestingly, drug and alcohol abuse was a rare condition among Cambodians, unlike the POWs.

Concentration Camp Survivors and the Global War On Terrorism

As a result of the global war on terrorism, detention centers for terrorist suspects or unlawful enemy combatants have been set up in Afghanistan, Iraq, and most published, Guantanamo Bay. These camps administered by United States military in no way match the horror of The Nazi or Khmer Rouge; however, evidence indicated that most detainees have been in legal limbo without an open and fair trial. As of June 2005, the United States was holding about 520 foreign terrorism suspects at Guantanamo Bay. Released prisoners, usually held for many years without charge, have alleged ongoing torture, sexual degradation, and religious persecution. As of August 2003, 29 inmates had attempted suicide (the more recent number is 34) and one-fifth of all prisoners were taking antidepressants. There are no studies on the effects of the experience of the detainees, but if other concentration camps can be a model, many will suffer long-term psychological changes and develop PTSD, depression, and other health problems. The very existence of such camps represents a profound moral and ethical challenge for democratic societies.

Summary

The concentration camp syndrome, as first described following the Nazi Holocaust, represented a

catastrophic stress and resulted in a common symptom pattern present in most survivors. These symptoms included marked anxiety, restlessness, startle reaction, sleep disturbances, nightmares, poor concentration, and excessive rumination about the traumatic events. The concentration camp syndrome was never recognized as an official American Psychiatric Association diagnosis but its symptoms are the core of what is now called PTSD. The symptoms have been found in other concentration camp survivors, such as POWs and the more recent Cambodian concentration camp survivors. The response is the result of extreme stress and indicates that such stress can produce a psychiatric disorder that is severe and persistent in many people.

An associated aspect of the disorder is the tendency to have reactivation on symptoms when further stress occurs. A real or symbolic threat can reproduce symptoms or behavior (such as extreme fear or nightmares) just as if the person were in the concentration camp. This speaks to the powerful memories that such extreme stress can cause, even though these memories may be repressed for a time.

Treatment of the concentration camp syndrome originally was not satisfactory, probably because the early methods used psychoanalysis (or similar techniques), which seemed too stressful for the patients. Current techniques using medication to reduce nightmares, sleep disorders, and hyperarousal, and supportive psychotherapy seem to help the patient integrate the experience and reconnect emotionally to others.

An emerging issue is that children of concentration camp victims also seem to suffer indirect effects and may be more vulnerable to PTSD than others. Even under the most extreme conditions, only about 50% of concentration camp victims suffer the full PTSD (concentration camp syndrome) or other physical or psychiatric disabilities. Reasons for this vulnerability of some and resiliency of others are unknown, but genetic factors are thought to play a part. The relationship between such massive psychological trauma and the development of psychiatric disorders is an important area of research.

The global war on terrorism has resulted in multiple concentration camps for detainees. Evidence is beginning to accumulate that torture occurs at such places and their may be severe long-term mental and physical for the survivors.

Glossary

<i>Allele</i>	One of two or more copies of a particular gene located on a chromosome.
<i>Androgens</i>	Sex steroids that stimulate the development of male sex organs and male secondary sexual characteristics.
<i>Azoospermia</i>	The complete absence of sperm in seminal fluid.
<i>Compound heterozygote</i>	A pair of alleles that are both mutated with abnormalities distinct from one another.
<i>Homozygote</i>	A pair of genes that are identical.

<i>Hyperplasia</i>	The increase in the size and number of normal cells in an organ or tissue.
<i>Hypogonadism</i>	A condition that results from the failure of sex steroid production.
<i>Phenotype</i>	The expression of the characteristics of a person as determined by his or her genes and influenced by environmental factors.
<i>Virilization</i>	The clinical consequences of excessive androgen production in females; characterized by temporal balding, a male body form, muscle bulk, deepening of the voice, enlargement of the clitoris, and hirsutism.

Congenital adrenal hyperplasia (CAH; previously known as adrenogenital syndrome) represents a diverse range of inherited disorders resulting from altered activity in the enzymatic steps required in steroid hormone synthesis. In each, cortisol production is reduced, leading to an increase of pituitary adrenocorticotrophic hormone (ACTH; corticotropin) secretion by negative feedback, which causes adrenal hyperplasia and the overproduction of either cortisol precursors or androgens. The incidence of the classic disorder is 1 in 5000–20 000 live births in most populations. This rate increases in certain specific geographic locations, including the Yupic population of

Alaska, the island of La Réunion, Brazil, and the Philippines. There is wide racial variation and phenotypic heterogeneity. Among Caucasians a 1/60 carrier frequency is found; in the Ashkenazi Jewish population, the carrier rate for nonclassic CAH is up to 19%.

Classification

CAH can be classified according to the specific type of enzyme deficiency involved. Classic CAH refers to the more severe form of enzyme deficiency with a prenatal, neonatal, or early childhood presentation. Nonclassic CAH represents a milder variant of the disorder, associated with less severe enzyme deficiency, a later presentation, and usually mild hyperandrogenism, often mimicking polycystic ovarian syndrome (PCOS). When presenting in adulthood, symptoms may be unmasked by various factors including cytochrome p450-inducing drugs such as anticonvulsants. CAH can also be classified as salt-wasting, non-salt-wasting, virilizing, or feminizing (see [Table 1](#)).

Molecular Genetics

The gene encoding the 21-OH enzyme is found on chromosome 6 (6p.21.3), and within this locus are both active and inactive (pseudo-)genes known as CYP21A2 and CYP21A, respectively. Most mutations involve the recombination of active and inactive genes, creating compound heterozygotes (i.e., different mutations on the two alleles) – with phenotype correlating with the less severely mutant allele – explaining the phenotypic variability of the disorder. Alongside common mutations, novel, highly variable

mutated alleles of CYP21A2 are increasingly being recognized, especially in the nonclassic phenotype. An unusual mechanism involving inactivating mutations of the P450 oxidoreductase enzyme causing simultaneous combined P450P17 and P450C21 deficiency has now been described in several families and provides significant insight into the pathophysiology of the disorder. Interestingly, *in vivo* this mechanism appears to confer a combination of androgen excess prenatally and androgen deficiency postnatally.

Biochemical Abnormalities

The family of disorders causing CAH are due to deficient activity (either the reduction in the amount of enzyme or impaired enzymatic function) in one of the five steps involved in cortisol biosynthesis ([Figure 1](#)). 21-Hydroxylase (21-OH) deficiency is the most frequent form. This enzyme converts progesterone to deoxycorticosterone and 17-hydroxyprogesterone (17-OHP) to 11-deoxycortisol in the endoplasmic reticulum (ER). Less commonly, deficient activity of 11 β -hydroxylase (11 β -OH) in the mitochondria or 3 β -hydroxysteroid dehydrogenase (3 β -HSD) and 17 α -hydroxylase (17 α -OH) in the ER can result in the syndrome. Last, the steroidogenic acute regulatory protein (StAR) is essential for transporting cholesterol to the mitochondria for steroid biosynthesis in the adrenal and gonad, and an abnormality in the gene encoding this protein leads to the very rare but devastating congenital lipid adrenal hyperplasia.

[Figure 2](#) illustrates the mechanism whereby deficient 21-OH enzyme activity leads to a decrease in cortisol production and an increase in adrenal androgen

Table 1 Classification and presentation of congenital adrenal hyperplasia at diagnosis^a

Deficiency	Salt-wasting	Virilization	Feminization (undervirilization)	Precocious puberty	Delayed puberty	Hypertension	Infertility, menstrual disturbance, hirsutism, and acne
21-OH (>90%)	Yes (not in late onset nonclassic cases)	Yes (severity varies)	No	Yes (possible presenting complaint)	No	No	Yes
11 β -OH (~5%)	No (almost all cases)	Yes (severity varies)	No	Yes	No	Yes (most cases)	Yes
3 β -HSD	Yes	No (mild or none at birth)	Yes (in males with classic cases)	Yes	No	No	Yes
17 α -OH	No	No	Yes	No	Yes	Yes	No
StAR	Yes	No	Yes	No	Yes	No	No

^a3 β -HSD, 3 β -hydroxysteroid dehydrogenase; 11 β -OH, 11 β -hydroxylase; 17 α -OH, 17 α -hydroxylase; 21-OH, 21-hydroxylase; StAR, steroidogenic acute regulatory protein.

and metabolic acidosis. Sodium conservation improves with age in some patients, although it is unclear why this should occur.

Virilization and precocious puberty In females, clitoral enlargement in early childhood may occur due to overproduction of adrenal androgens. In males, the penis may enlarge but the testes remain small. In both, pubic hair growth may occur early and excess linear growth with concomitant epiphyseal closure is common. Circulating androgens may prematurely activate the hypothalamic-pituitary-gonadal axis, and the child may have true precocious puberty. Short stature due to premature epiphyseal closure invariably occurs unless the condition is treated early.

Delayed puberty Delayed puberty is a rare manifestation of CAH and can occur in poorly controlled 21-OH deficiency with the suppression of gonadotropins by excess adrenal androgens.

Primary amenorrhea Primary amenorrhea is an uncommon presentation that may occur in less severe variants of 17 α -OH deficiency or 3 β -HSD deficiency when phenotypic females with poorly developed secondary sexual characteristics (breast development and pubic hair) fail to menstruate due to deficient production of ovarian estrogen.

Impaired fertility A degree of impaired fertility found in some patients is multifactorial. Live birth rates resulting from patients with classic CAH continue to improve – ovulation may be spontaneous or assisted by clomiphene and/or gonadotropins.

Nonclassic Congenital Adrenal Hyperplasia

Nonclassic forms of CAH have their onset of symptoms in late childhood or in adulthood.

Precocious puberty Less severe forms of CAH with no evidence of salt-wasting can present for the first time in later childhood. Accelerated linear growth and bone age can result in reduced ultimate adult height unless the correct diagnosis is made and treatment given.

Hypertension In those types of CAH in which excess mineralocorticoids are produced, hypertension may result, which may become apparent only in later life.

Acne and hirsutism in the female Nonclassic types of CAH with excess androgen production can be

indistinguishable from those women with polycystic ovaries, which are frequently present on ultrasound. Approximately 1–3% of hyperandrogenism in adult females is due to late-onset CAH.

Impaired fertility and menstrual disorders Fertility can be impaired in both males and females with CAH. In females, this is due to excess progesterone and androgens suppressing the normal cyclicity of the hypothalamic-pituitary-gonadal axis plus various factors affecting fertilization and implantation. In males, azoospermia may be reversed with glucocorticoid replacement and various forms of assisted conception.

17 α -Hydroxylase Deficiency

The specific condition of 17 α -OH deficiency deserves highlighting due to the resultant deficiency of sex steroid production. It exhibits marked phenotypic heterogeneity, with a disproportionately higher prevalence found in Brazil. There may be a severely impaired development of external genitalia in both sexes; genotypic males are usually raised as females due to a lack of *in utero* and postnatal male phenotypic development. In addition, the mechanism of this metabolic defect generates excess mineralocorticoid with its associated clinical features.

Diagnostic Investigations

Once the clinical suspicion is raised, the diagnosis of CAH can be made by measuring the level of steroid precursors in the basal state (see [Table 2](#)) or after ACTH stimulation (see [Figure 3](#)). 17-OHP can also be measured in saliva; examining the urinary steroid profile for abnormal concentrations or ratios of metabolic products of the various steroids can be diagnostic (see [Table 2](#)). The adrenal glands can be imaged by ultrasound, computed tomography (CT) scan, or magnetic resonance imaging (MRI) and may show evidence of bilateral hyperplasia in contrast to the focal lesion, which may be seen with an adrenal tumor. Prenatal diagnosis can be made by the measurement of 17-OHP or androstenedione in amniotic fluid. Human leukocyte antigen (HLA) typing and linkage analysis of cultured fetal cells from chorionic villus sampling in the first trimester or amniocentesis later in gestation can reliably predict genotype for 21-OH deficiency. Automated sequencing and polymerase chain reaction using DNA extracted from uncultured or cultured fetal cells can be employed to screen for specific mutations in the genes responsible for CAH.

Treatment of Congenital Adrenal Hyperplasia

The aims of treatment are usually to correct cortisol and mineralocorticoid deficiency and to suppress adrenal androgen production, thereby preventing virilization. If successful, this should allow normal maturation, growth, development, and fertility in adult life. The patient should be monitored for the potential adverse effects of overtreatment with glucocorticoids.

The daily dose of glucocorticoid therapy should correspond to the normal adrenal production rate of approximately 7 mg/m²/day usually given in split dosage. The decision on dosage schedule and preparation of replacement glucocorticoid is still controversial. Larger dosing at night with longer-acting, more potent glucocorticoids such as dexamethasone decreases the exaggerated morning ACTH (and also adrenal androgen) peak of the circadian rhythm but theoretically can suppress nocturnal growth hormone

release. The dosage of glucocorticoid should be increased two- to threefold in the event of a febrile illness, and for more severe stresses higher doses or even parenteral therapy may be required. The theoretical concern in relation to the bone density effects of glucocorticoids does not appear to be borne out by the evidence available from carefully treated patients. Glucocorticoids are not used for replacement in the treatment of nonclassic CAH but are used to suppress adrenal hyperandrogenism by inhibiting the morning ACTH peak by delivery of small doses of dexamethasone (e.g., 0.5 mg) or prednisone (e.g., 5 mg) at night. In the nonclassic and classic variants, an antiandrogen can be used in combination with glucocorticoids to treat symptoms of hyperandrogenism.

The adjustment of the dose of glucocorticoid depends on clinical assessment combined with the results of monitoring in the cases of 21-OH deficiency, 17-OHP, adrenal androgens, and/or urinary 17-ketosteroid production. These are, however, not ideal biomarkers, and efforts continue to find more specific ways of monitoring the disease.

Mineralocorticoid replacement therapy with 9 α -fludrocortisone should be used in all those patients with salt-wasting forms of CAH. The use of mineralocorticoid therapy in nonclassic late-onset variants of the disorder with raised plasma renin activity, which reflects salt loss, often allows a reduction in the dosage of glucocorticoid and subsequently less risk of iatrogenic side effects. Renin levels can be used in the monitoring of fludrocortisone dosage. In refractory cases, especially when subfertility, obesity, and hirsutism may be prominent features, adrenalectomy is sometimes performed, followed by adrenal steroid replacement.

Prenatal treatment of affected females *in utero* with dexamethasone to prevent virilization of the fetus has been used with varying success. To be effective, treatment must be started at less than 10 weeks (preferably 5–7 weeks) gestation and continued until delivery in affected females but discontinued in males and unaffected females. Mendelian inheritance dictates that without diagnostic confirmation, treatment will only be appropriate in one out of eight fetuses. Maternal side effects such as weight gain, hypertension, diabetes, and edema are common but fortunately more severe side effects are rare. This field lacks consensus, and registries have been created in certain locations, such as Sweden, where the gold standard is that treatment is provided only within the framework of a prospective trial.

The timing of corrective surgery and correct gender assignment is the subject of much debate, with earlier single-procedure operations becoming more popular. There is still controversy over the ideal mechanisms

for assigning gender, and multidisciplinary teams have been found to be the optimal strategy for handling the delicate issues involved. In severe forms of 21-OH and 11 β -OH deficiency, virilization may be so severe that genotypic females may need to be raised as males and ovariectomy will be required with prostheses inserted into the scrotum at puberty. There is evidence that exposure to androgens *in utero* can alter gender and sexual identity in affected females, in whom there is an above-average increase in tomboyish behavior and lesbianism. These sequelae demonstrate the need for early and adequate treatment of the condition and long-term follow-up to ensure well-balanced individuals, progress through puberty, and the formation of stable relationships. Sexual function in adulthood is an area of increasing discussion, and the psychosocial impact of this condition has only recently been fully explored.

Conclusion

CAH is a heterogeneous condition that causes multiple imbalances in metabolic pathways of steroid hormone synthesis. Knowledge of the genetic basis for the condition has allowed increasingly specific methods of screening and treatment to be developed.

Corollaries of Conservation of Resources Theory

Conclusion

Glossary

Conservation of resources (COR) theory

States that stress has central environmental, social, and cultural bases in terms of the demands on people to acquire and protect the circumstances that insure their well-being and distance themselves from threat to well-being.

Resources

Those objects, personal characteristics, conditions, or energies that are valued by the individual or that serve as the means for attainment of other objects, personal characteristics, conditions, or energies.

High-risk situations such as war, terrorism, natural disasters, and crime and victimization as well as the onset of a serious illness put people's coping resources to a test and can result in psychological stress and distress. Because these situations are widespread, it is important that we examine the effects that high-risk situations have on people and why some can go through them relatively unscathed, whereas others are almost completely debilitated. As many as 2 million American households experience injuries and physical damage each year from fire, floods, hurricanes, tornadoes, and earthquakes. Over the past two decades, natural disasters and other calamities have killed about 3 million people worldwide and adversely affected the lives of at least 800 million more people. Between 1974 and 1980, there were 37 major catastrophes in the United States alone. In addition, few families are spared the pain of having a family member who has a serious illness or one who passes away.

Although in the United States we think of war as something that does not affect us directly, global conflict is widespread, and communications have forced us to share in the suffering many go through in wars elsewhere. The events of September 11th, 2001 in the form of the attack on the World Trade Center in New York and the Pentagon in Virginia made terrorism all too real for Americans as well. This article explores conservation of resources theory as applied to high-risk situations as one theoretical backdrop for explaining the differences in people's coping successes and their subsequent psychological reactions.

Conservation of Resources Theory

Conservation of resources (COR) theory examines and describes the nature of psychological stress and its likely consequences. Traditionally, stress theories have concentrated on people's individual appraisals of stressful situations as the determining factor of how much distress they will experience. COR theory states that stress is neither first nor foremost a product of individuals' appraisal of events, but that it has central environmental, social, and cultural bases in terms of the demands on people to acquire and protect the circumstances that ensure their well-being and distance themselves from threats to well-being. COR theory posits that stress emanates from difficulty achieving the common goals toward which members of a culture strive. In this regard, stress is largely culturally determined because most of the major demands placed on people have a shared social context and that culture is a social phenomenon. Through personal experience and learning, people come to recognize what they need in order to affirm the acquisition and ownership of what is important directly, indirectly, and symbolically for success within their culture and for sheer survival. These things that individuals value are called resources.

Resources

Resources are those objects, personal characteristics, conditions, or energies that are valued by the individual or that serve as the means for attainment of other objects, personal characteristics, conditions, or energies. COR theory's basic tenet is that people strive to retain, protect, and build resources and that what is threatening to them is the potential or actual loss of these valued resources. In addition, people also endeavor to foster that which they value. Therefore, people work to acquire resources that they do not have, preserve those resources they have, protect resources when they are threatened, and cultivate

resources by positioning themselves so that their resources can be put to best use.

Stress occurs in circumstances that represent a threat of loss or actual loss of the resources required to sustain the individual-nested-in-family-nested-in-social-organization. Further, because people will invest what they value to gain further, stress is predicted to occur when individuals do not receive reasonable gain following resource investment, this itself being an instance of loss.

It follows that psychological stress is a reaction to the environment in which there is (1) the threat of a net loss of resources, (2) the net loss of resources, or (3) a lack of resource gain following the investment of resources. Individual-nested-in-family-nested-in-social-organization implies that these levels are enmeshed because there is no organization or family without individuals and individuals must rely on social attachments for well-being, self-esteem, and survival.

Resource Categories

COR theory identifies resources whose loss is likely to result in stress. Since there is a common basis of human survival, most of these resources are valued across cultures, whereas others are more culturally or familially determined. Three different methods have been considered to categorize these resources. The first method categorizes resources into internal and external types. Several researchers have used this distinction. Internal resources are those that are possessed by the self or are within the domain of the self. This includes resources such as optimism, self-esteem, and a sense of mastery. External resources are those resources that are not provided by the individual, but are external to it. These include resources like social support, employment, and economic status.

Another method of classification of resources is a structurally based system that divides resources that have meaningful differences. The resulting four resource categories are (1) object resources, (2) personal resources, (3) condition resources, and (4) energy resources. Object resources (e.g., shelter, transportation) are valued because of some aspect of their physical nature or because of their acquiring secondary status values based on their rarity and expense. Personal characteristics are resources to the extent that they generally aid stress resistance. These include both skills and personal traits. Some examples of these are social competence, self-esteem, and a sense of mastery. Conditions are resources to the extent that they aid in obtaining other valued conditions or are themselves goals that people value. Some examples of condition resources are marriage and

tenure. These resources are important because they lay the structural groundwork for access to other resources. Energies include resources such as time, knowledge, and money. They acquire value from their ability to be exchanged for resources in the previous three categories. Because of the common basis for human survival, many resources are valued across cultures. However, the order of importance of resources will vary along with differing cultural values, and some resources may be present in some cultures and not others.

The third method of classification of resources is based on the proximity of the resource to survival. Primary resources are those that directly correlate to survival. These include ample food, shelter, safety, and clothing. Secondary resources are those that contribute indirectly to primary resources. These include social support, marriage, and optimism. Tertiary resources include those things that are symbolically related to primary or secondary resources. These include money as well as workplace and social conditions that allow availability or access to secondary resources and resources that signify social status.

Principles of Conservation of Resources Theory

Principle 1

There are two major principles that follow from the basic proposition of COR theory. The first principle is that *resource loss is disproportionately more salient than resource gain*. Therefore, given an equal amount of loss and gain, loss will have a much greater impact. According to COR theory, it is the loss and the threat of loss of resources that principally define stress. This principle has also been developed in work by Tversky and Kahneman in their prospect theory. Their theory states that the gradient of loss is steeper than the gradient for gain, which results in a bias in favor of loss. In experiments they have shown that when problems are framed or worded in terms of loss, greater risk will be taken to try to preserve resources than if the same situation is framed in terms of potential gain. Studies that separate loss from gain events also confirm that only loss events are related to psychological distress and illness. Therefore, it appears that losing resources will be much more notable and will have a greater impact than the equivalent gain.

If loss is more salient than gain, resource loss should have a greater impact on psychological distress than gain. This was examined empirically. First, groups of students, community members, and psychologists nominated resources that they valued.

Next, different groups of people added resources that they felt were important that did not already appear on the list and deleted resources they felt were not valued. This process was repeated with about 50 different groups until no new resources were added that had not been deleted by more than one group prior and until no new deletions were judged to be necessary, ending with a final list of 74 resources.

Next, 255 students and 74 community members indicated whether they had lost or gained each of the 74 resources recently as well as during the past year. They repeated this process twice, separated by 3 weeks. They were also administered well-known anxiety and depression scales. Results indicated that neither recent resource gain nor resource loss during the past year had any direct impact on psychological distress for either group. Recent resource loss and resource loss during the past year, in contrast, had major negative effects on psychological distress. People were deeply negatively effected when they lost resources, but were hardly impacted when they experienced resource gain.

Researchers have applied COR theory to study the impact of both Hurricane Hugo, which affected South Carolina in 1990, and the Sierra Madre earthquake that hit Los Angeles county in 1991. They examined how resource loss influenced the mobilization of resources and also how loss effected mental health. It was found that the greater the resource loss, the more coping individuals engaged in and the more psychologically distressed they became. They also found that the influence of resource loss was both of greater magnitude and independent of the influence of positive coping responses. Supporting COR theory, resource loss was more important in predicting psychological distress than were personal characteristics and coping behavior.

The impact of resource loss on coping, physical health, and psychological well-being was examined further after Hurricane Andrew struck South Florida in 1992. Comparing the impact of resource loss to other factors, it was found that resource loss had the single most profound influence. The greater the resources people lost, the greater was their psychological distress and the worse their immune resistance. It was also found that individuals' sense of optimism counterbalanced much of the negative influence of resource loss. Therefore, those people who had resources, including optimism, were more likely to successfully cope with Hurricane Andrew than did those individuals who lacked resources.

Traumatic stress entails the rapid loss of resources and the resources lost are usually the ones held with highest value by individuals. The rapidness of

resource loss is related to the fact that traumatic stressors (1) attack people's most basic resources, (2) typically occur unexpectedly, (3) make excessive demands on remaining resources, (4) are outside of the realm for which resource utilization strategies have been developed, and (5) leave a powerful mental image that is easily evoked by cues associated with the event. The excessive demands placed on an individual by a war or natural disaster are such that no amount of resources could prevent severe initial reaction to stress. At best, it is expected that a healthy individual could make a reasonably rapid recovery that could be a matter of weeks, months, or years, depending on the trauma. For many traumatic events, it would be expected that negative sequelae be lifelong, but hopefully limited to certain life domains so that most normal functioning continues.

Chronic stressful conditions also have been found to chip away at resources and strong resource reservoirs. For example, social support has been found to diminish for mothers of chronically ill children and for women with breast cancer. In addition, under chronic stress conditions, resources that remain have been found to have increasingly limited effectiveness. This may be the case because loss begets further loss and can lead to loss spirals. Under a chronic stressful condition, not only do people experience more and more loss, they also may deplete resources until they have few resource reserves to contribute to the stress resistance process. For this reason, COR theory has also become a major explanatory system for understanding the stress of burnout in the workplace. In burnout, resources are slowly depleted to produce exhaustion, alienation, and psychological distress.

Although loss is more salient than gain in COR theory, resource gain is an important facet of stress, even if it is secondary. Resource gain is important because it is woven with loss. Loss can be prevented, counterbalanced, or forestalled through resource gain. If initial losses occur, previously stored resources can be applied to minimize the impact of loss. Resource gain also increases in meaning in the face of loss. This occurs because people take stock of their resources when loss occurs. People enact gain cycles in the wake of loss, in part to offset current resource loss, but also because they become more aware of future losses and look to prevent them. Consistent with the idea that resource gain is important in the face of loss, researchers examining workers who were laid off from their jobs found that those people with financial savings did not experience the harmful effects of unemployment. However, they found that prior to the worker's job loss, their savings

had little positive impact, supporting the idea that resource gain or surpluses (in this case a savings account) increases in significance during a loss.

Principle 2

The second principle that follows from COR theory is that *people must invest resources in order to protect against resource loss, recover from loss, and to gain resources*. COR theory states that resources are central to the experience of stress. Stress occurs when resources are lost or threatened, and people use resources to prevent or offset loss and to make other resource gain. This investment of resources occurs by several mechanisms. The first mechanism of resource investment deals with the total investment of a resource. The second kind of resource investment involves risking the resource without total investment. Resource investment may also occur directly or through substitution. Resource investment may counterbalance loss, protect against threat of loss, or contribute toward resource gain.

When mastery, optimism, social support, finances, or status are put into place to offset a major stress event, the importance of principle 2 is underscored. First, the resource must be ample enough to be used. Low self-esteem will have limited value, just as little money can do little good to offset financial losses. The second principle of COR theory also suggests a more subtle point. Specifically, because people typically have little experience with major stressors, they may not know how to employ their resources in these special circumstances. Just as combat troops must learn to apply their skills under increasing pressure, people will learn and adjust to even catastrophic circumstances. However, the cost of resource investment will accelerate as people will at first misuse resources, hold back on resource use to preserve resource integrity, and will need to allow for a quick depletion of resources in some instances.

Corollaries of Conservation of Resources Theory

Corollary 1

In addition to the two major principles presented previously, there are four corollaries of COR theory that outline rules that allow for definitive predictions as to how resources function over time. The first corollary states that those with greater resources are less vulnerable to resource loss and more capable of orchestrating resource gain. Conversely, those with fewer resources are more vulnerable to resource loss and less capable of achieving resource gain. Moreover, those who lack resources are more likely to

experience extreme consequences, as without adequate resource reserves they are less likely to have resources to invest in the wake of initial losses.

Resources may be used either individually or in combination with other resources. In addition, stress often makes multiple demands on people that require different combinations of resources. However, those people with greater resources will be less negatively affected by initial resource loss and will be more likely to create gain cycles because they can invest resources that are not required for everyday functioning. Those people with fewer resources will be more deeply impacted by a major crisis or by chronic demands and will have few resource reserves to assemble. Therefore, initial setbacks will be devastating and result in immediate and rapid loss spirals.

Corollary 2

The second corollary of COR theory states that *those who lack resources are not only more vulnerable to resource loss, but that initial loss begets future loss*. People rely on resources to apply to losses, and therefore with each loss there are fewer resources that can be utilized or invested in gains that might influence the occurrence of stress. With a depleted resources pool, future challenges are increasingly less likely to be met and a downward spiral increases in momentum. This results in depleted resource reserves that are less capable of mobilizing to defend against future challenges. This further suggests that loss cycles will have initially higher velocity for resource-poor individuals or groups, as they are from the outset in a resource-challenged state characterized by their resources being already stretched in protection of the self, family, or social system. Therefore, this corollary predicts that loss cycles will have progressing momentum and strength.

When exposed to very high risk situations, people may lose not only their tertiary and secondary resources, such as transportation and a sense of mastery, but also may lose primary resources, such as food and shelter that are necessary for survival. In this way, the psychological stress that people experience in a high-risk situation is not only taxing because of its severity, but also because of the vast array of resources that it may effect and deplete. Hence, in studies of the impact of September 11th, psychosocial and material resource losses were the most major predictors of posttraumatic distress.

When individuals are not equipped to gain resources, especially if they are in a loss spiral, they are also likely to be particularly vulnerable. For example, in many disasters such as war, the country may be in such turmoil that it is very difficult for

people to gain resources such as employment or money. Individuals may also not be equipped to gain resources because they might have limited access to opportunities to protect themselves or to gain access to the resources available to others in society. Furthermore, resources are not distributed equally in society, and those people who lack resources are most vulnerable to additional losses. Those with weak resources have been found to have the least success under high stress. Loss spirals develop because people lack the resources to offset the cascading of loss. If resources are used to prevent loss of other resources, such loss would be predicted to lead to further decreases in the likelihood of possessing necessary resource reserves. In this manner, people who have weak or few resources prior to the onset of a high-risk situation, like a natural disaster, will psychologically do worse and will experience more loss spirals than those who had stronger or greater resources prior to the disaster.

Environmental circumstances, like high-risk situations such as war, natural disasters, chronic illness, and rape, often threaten or result in multiple depletions of people's resources. These losses are important because resources have instrumental value to people and they have symbolic value in that they help to define for people who they are. Hence, rapid resource loss impacts people's ability to mobilize resistance resources as challenges to the social fabric that binds communities and sustains people as a safety net. Further, ongoing major losses ebb away at people's sense of identity that may result in helplessness and other extreme behaviors evidenced in panic, mob action, and even barbarism.

Corollary 3

The third corollary of the COR theory states that *those who possess resources are both more capable of gain and that initial resource gain begets further gain*. If initial resource gains are made, then greater resources become available for investment. When initial gains are achieved, additional resources become available for investment and individuals and social systems are less vulnerable to loss and loss spirals. In addition, individuals do not necessarily need to rely on these resource surpluses for reserves, so they can benefit further by employing them for gains' sake. However, because resource loss is more potent than resource gain, gain cycles will have less momentum or speed and less impact than loss cycles and people will be motivated to sustain resistance reserves for future misfortune. Seen in this light, in the case of major and traumatic stress, gain cycles will often only occur well after the events' initial impact. Even then,

gain cycles will often begin from a depleted base and might better be framed as rebuilding cycles.

Corollary 4

The fourth and final corollary affirms *that those who lack resources are likely to adopt a defensive posture to guard their resources*. For those with few resources, the cost of resource investment surpasses demands and makes the individual or organization vulnerable. A defensive posture keeps a maximum of resources in reserve in case the person needs to offset a future loss.

Those people who lack resources are predicted to take a defensive posture in order to guard their resources. Those with weak resources have been found to use their resources best when challenged by everyday stressors, but to have the least success under high-stress conditions. In studying victims of Hurricane Andrew, researchers found that resource loss resulted in a marked increase in use of denial coping. This, in turn, placed victims at increased risk for PTSD. To expend resources from a depleted system may be too risky a venture. Instead, a shutdown response may best preserve limited resource pools until the storm (literally in this case) blows over.

Conclusion

In conclusion, loss is particularly salient because it is disproportionately weighted in the human experience and it is harder to prevent loss than to obtain resource gain. Therefore resource loss is more powerful and more potent than resource gain. COR theory states that when loss occurs it is more depleting of resources than gain is resource generating. It is clear that high-risk situations deplete resources as well as resource reserves and can result in loss spirals. COR theory defines psychological stress as a reaction to the environment in which there is the threat of a net loss of resources, the net loss of resources, or a lack of resource gain following the investment of resources. In high-risk situations such as war, natural disasters, or sudden illness, many if not all of these threats can occur. Therefore, COR theory would explain people's distress following a high-risk situation not as an individualized response based solely on characteristics of the individual, but as one that occurs because of the threats to resources as shared within a community.

Although loss is more salient than gain, this is not to imply that resource gain is not important. Resource gain is important because it can prevent, counterbalance, or forestall loss. However, in a

high-risk situation, many factors may prevent resource gain and therefore limit the role of gain in forestalling loss cycles. Because of the long tail of resource loss that follows major stressful circumstances, follow-up to protect the individual and social system are needed on a long-term basis.

Behavioral Control and Physiological Stress Responses

Perceived Control

Cognitive Control and Coping

Control and Well-Being

Conclusions

Glossary

<i>Behavioral control (instrumental or objective control)</i>	The situation when the organism has at its disposal a behavioral response that can prevent, reduce, or terminate stressful stimulation.
<i>Cognitive control</i>	A form of psychological coping related to perceived control over one's reactions to aversive events.
<i>Locus of control</i>	A set of generalized control beliefs concerning the extent to which individuals feel that aspects of their lives are determined by their own activities and abilities (internal locus of control) or are governed by external factors.
<i>Perceived control</i>	The belief that one can exert control over stressful events, based on the appraisal of the situation and appropriate perceptions of competence (self-efficacy expectancies) and expectations concerning the outcome of making a response.

Stressors come in many guises, for example, confrontation with a predator, death of a close relative, conflict at work, or living in crowded noisy conditions. When we try to understand what aspects of situations make them more or less threatening, the concept of control emerges as a crucial feature. Stressors differ in the extent to which they can be controlled, and behavioral control is typically associated with a diminution of stress responses. Sometimes the perception of control is sufficient to reduce stress reactions, even though control itself is never actually exercised. For example, studies of people who are anxious about dentistry have shown that telling people they can give a signal that will stop the procedure reduces pain and anxiety, even though they never use the signal. Humans

and other animals also seek out information about impending threatening events and ways of coping with the situation. This phenomenon is known as cognitive control and is an important weapon in the armory of psychological coping. Finally, there are control beliefs or the sense of control that people have in specific areas or over their lives and destiny more generally. A sense of control is generally adaptive for health, but the need for control may under some circumstances be maladaptive and lead to an inflexibility in coping with difficult problems. Since control has so many facets, there is a danger that the construct is misused and disguises careless reasoning. In this article, the different aspects of control and stress are described, along with evidence related to physiological responses, well-being, and health. The ways in which control can be enhanced to improve quality of life, ameliorate pain, and promote rehabilitation are also discussed.

Behavioral Control and Physiological Stress Responses

Behavioral control can be defined as having at one's disposal a behavioral response that can prevent, reduce, or terminate stressful stimulation. Natural stressors vary across the entire spectrum of controllability. Some events, such as the unexpected death of a family member, are outside personal control. But in many situations there is an element of behavioral control. People who regularly find themselves stuck in traffic jams on their morning journey to work may feel helpless, but actually have some control; they might choose to use some other form of transport, to start their journey at a different time, to select a different route, to stop and take a break until the traffic clears, and so on.

Study of the impact of behavioral control over stress is complicated by the fact that many of the most aversive life events are uncontrollable. Comparisons between controllable and uncontrollable events may therefore be confounded with the aversiveness of the experience. Experimental studies provide the best opportunity to examine the effects of behavioral control, since aversiveness can be held constant. The yoked design championed by Jay Weiss and later by Martin Seligman and others has served to illustrate the effects of behavioral control most clearly. In this paradigm, a pair of rodents is exposed to identical intermittent aversive stimuli (electric shocks or loud noise). One animal is able to make a behavioral response that either terminates the stimuli or delays

Table 1 Adverse effects of uncontrollable stress in comparison with exposure to matched controllable aversive stimulation

Decreased food/water consumption
Greater weight loss
Higher plasma corticosterone
Increased gastric lesions
Reduced production of specific antibodies
Reduced lymphocyte reactivity
Decreased cytotoxic activity of natural killer cells
Decreased tumor rejection
Increased susceptibility to malignancy

their onset, while the second animal has no response available. The amount of aversive stimulation experienced by both depends on the effectiveness of the performance of the one in the behavioral control condition, and any differences in physiological responses or pathology will result from the availability of behavioral control.

Table 1 summarizes some of the many physiological and pathological advantages conferred by control in this design. It can be seen that behavioral control is associated with amelioration of physiological stress responses and pathological outcomes. These range from reduced levels of neuroendocrine response to slower proliferation of experimentally implanted malignancies. The regions of the brain responsible for these effects have been identified. Uncontrollable stressors appear to sensitize serotonergic neurons in the dorsal raphe nucleus, while this activation is blocked by projects from the central medial prefrontal cortex when stressors are controllable. But not all the biological responses to uncontrollable stress are detrimental. For example, uncontrollable conditions tend to lead to greater stress-induced analgesia than matched controllable conditions, and this mechanism may permit organisms to endure stressful stimulation at a reduced level of physical discomfort.

Research in humans has gone some way toward duplicating these effects, with differences in the magnitude of acute cardiovascular and endocrine responses. However, an important caveat concerns the effort or response cost associated with maintaining behavioral control.

Control and Effort

Effects of the type shown in **Table 1** have generally emerged in studies in which behavioral control is easy to exert. For example, electric shock may be avoided by a lever press on a simple schedule of reinforcement. However, control may require great effort to maintain and can be associated with a degree of uncertainty as to whether it has been successful.

Under these circumstances, physiological activation may be greater than that elicited in uncontrollable situations. This was illustrated in the classic human experimental studies carried out by Paul Obrist. Obrist randomized human volunteers to three conditions in a shock avoidance reaction time study. All participants had to respond rapidly to aversive stimuli and were informed that successful performance would lead to avoidance of electric shock. Three criteria were employed: an easy condition in which even slow reaction times would be successful, a hard condition in which participants had to maintain or improve performance over time, and an impossible condition in which the reaction time criterion was too fast for most people. The impossible condition is comparable to uncontrollable stress, while the other two conditions represent easy and effortful behavioral control, respectively. The number of shocks administered was held constant across conditions. It was found that the greatest physiological activation was present not in the impossible or uncontrollable condition, but in the hard condition. This physiological reaction pattern was sustained by selective activation of β -adrenergically mediated sympathetic nervous system responses. Later studies have established that the enhanced physiological reactions associated with control under these circumstances are related to the effort expended, with greater effort being correlated with heightened norepinephrine responses.

Control and Fear

Lack of control over aversive stimuli potentiates fear responses. Using the yoked control design, it has been found that rats subsequently placed in a different environment and given two brief shocks so as to generate conditioned fear showed greater freezing responses if they had previously had no control over shock compared with those that had had control. These effects are long-lasting, but can be blocked by benzodiazepines. Fear responses associated with uncontrollable stress are again related to release of serotonin in the dorsal raphe nucleus and amygdala. Experiments using *in vivo* microdialysis have shown that uncontrollable stress leads to increased levels of extracellular serotonin in both these sites, while animals exposed to controllable stress show no such elevation.

Research on humans also suggests that control is relevant to fear responses. Fear of pain during medical and dental procedures is strongly associated with perceptions of uncontrollability. Fear of social threats (for example, when the individual is threatened with physical or sexual assault) is greater when people believe the situation is uncontrollable.

Control and Work

Control is important to understanding the physiological and health consequences of stressful events in human life. One area in which control has emerged as a key variable is in the study of work stress. Jobs vary on many dimensions of control. Some work is self-paced, while other tasks are externally paced by machines or other people. In some jobs, workers have choice about their posture, when they can take rest breaks, and how the work should be done. Flexibility in work hours, participation in decision making, and autonomy at work are all factors that vary across jobs. In psychophysiological studies, it has been found that cardiovascular and neuroendocrine activation is greater during externally paced than self-paced work, even when the actual pace of work is held constant. The same patterns are present in the real work environment. Figure 1 illustrates the pattern of ambulatory blood pressure measured every 20 min over the working day in middle-aged men and women divided into low and high job control on a standard questionnaire measure. Ambulatory

pressure was greater throughout the day in people working in low-control jobs after controlling statistically for covariates.

Several prospective epidemiological observational studies have evaluated the demand/control model of work stress. They have shown that low control at work, either alone or in combination with high demands, predicts future coronary heart disease in previously healthy adults independently of standard disease risk factors. It has also been found that control over work pace influences health during pregnancy, and that women with lower control jobs may be at greater risk for preeclampsia and low back pain, after statistical adjustment for age, parity, education, smoking, and type of work.

Conversely, greater autonomy and participation at work promote higher levels of self-reported job satisfaction, commitment to work, better performance, and reduced levels of emotional distress, staff turnover, and absenteeism. However, these studies of work illustrate a complication in human research in control, since it is clear that control cannot be seen solely as an objective characteristic of the environment, but depends on subjective perceptions.

Figure 1 Mean systolic blood pressure (a) and diastolic pressure (b) in the morning, mid-day, afternoon, and evening periods in high (dashed line) and low (solid line) job control groups, adjusted for gender, employment grade, age, body mass index, smoking status, and physical activity. Error bars are standard errors of the mean. From Steptoe and Willemsen (2004). *Journal of Hypertension* 22, 915–920.

Perceived Control

Perceived control is the sense that one has control over aversive events. Objective differences in behavioral control are presumably mediated by perceived control. Thus, the benefits of having control over a particular aspect of work (such as being able to make a personal telephone call if necessary) will be apparent only if the worker realizes that this option is available. Perceived control is the result of a subjective judgment based on the individual's appraisal of the situation. It has two elements. The first is a perception that the situation is potentially controllable, and the second is that the individual can take the correct action. There may be circumstances in which events are perceived as controllable, but no action is taken since people lack (or believe they lack) appropriate behavioral competence. Psychologists such as Albert Bandura have postulated a distinction between outcome expectations and self-efficacy expectations to characterize these two aspects.

It is generally found that distress is associated with a perception that events are uncontrollable, and this phenomenon may operate independently of objective behavioral control. Thus, two individuals may experience the same event, such as the breakdown of an important personal relationship. One may perceive that the event was outside his or her control, due to the callousness of his or her partner, the circumstances in which they lived, or the predatory behavior

of a third party. Another person may perceive him- or herself to have been responsible; if the person had not been preoccupied with work or had responded better to the needs of his or her partner, then the relationship might not have floundered. One student who has failed an academic examination may attribute this to lack of preparation and effective revision, while another may blame arbitrary examiners or bad luck in the selection of questions.

Human beings seek to understand their experiences in life by developing explanations for aversive events and often construe events retrospectively as having been controllable (for example, "If I had not stayed later than I planned at that party, and had not decided to walk down that street, I would not have been assaulted"). Such cognitive attributions may be maladaptive in leading to self-blame for occurrences over which one has little control, but also may help to impose sense and order on a world that may otherwise appear cruel and arbitrary.

Sense of Control

Perception of control is not restricted to individual aversive experiences, but also relates to domains of life or even to life in general. The term locus of control is used to describe these generalized control beliefs. This construct was first introduced by Rotter, who argued that people varied in the extent to which they believed that important outcomes were determined by their own internal abilities and activities or by external factors. The idea of locus of control has since been elaborated upon in two important ways. First, locus of control may be domain specific, with different levels of belief in personal control over different aspects of life (health, work, personal relationships, etc.). Thus, people may feel a strong sense of control over their work, but believe that their living environment (traffic, difficult neighbors, etc.) is out of their own control. Second, it may be useful to understand locus of control as consisting of three dimensions: belief in internal control, chance, and powerful others. For example in the domain of health, people can be categorized according to the extent to which they believe that their health is determined by their own actions (internal control), that whether they remain healthy is a matter of fate or luck (belief in chance), and that their health is influenced by the competence of doctors and other health professionals (belief in powerful others). A dimensional perspective implies that people may simultaneously hold strong beliefs about more than one set of influences. They may believe, for instance, that they have quite a lot of control over their health, while at the same time believing that doctors are also very influential.

Sense of control is an individual belief pattern that also has developmental and social determinants. Animal studies indicate that monkeys provided with experiences of controllable (contingent) events early in life are subsequently less reactive to stressful events in adulthood. The experience of a major uncontrollable event in childhood, such as the death of one's mother, is associated with increased likelihood of depression following negative life events in adult life. Differences in sense of control may also relate to social class, with economically more deprived people facing greater external obstacles and fewer opportunities to influence events than the better off. One study assessed sense of mastery (e.g., agreement with the statement "Whether I am able to get what I want is in my own hands") and perceptions of constraints (e.g., "There is little I can do to change many of the important things in my life") in three large population surveys. It was found that sense of mastery was greater in higher than in lower income sectors of the sample, while perceived constraints were less. The financially better off also reported greater life satisfaction and less depression and rated their health as better. However, not all the lower income respondents had low mastery and high constraint ratings. Some individuals in the low-income sectors had high mastery ratings, and they reported greater life satisfaction, less depression, and health levels comparable with those of the high-income group.

Sense of control has cultural and political determinants as well. Surveys in Eastern Europe during the first decade after the collapse of communism identified a profound sense of lack of control over life, as people witnessed the destruction of familiar institutions and ways of life and experienced greater difficulty in fulfilling daily needs. Those years were characterized by a rapid deterioration in health and well-being in many sectors of the population of Russia and several Central-Eastern European countries.

Cognitive Control and Coping

Another closely related phenomenon is cognitive control, which can be defined as the belief that one can control one's reactions to events. It is a common characteristic to seek out information about events even when they cannot be controlled behaviorally. The person who has an abnormal result on a medical test and is scheduled for further examination may try to find out about the test and its consequences from acquaintances, the Internet, or other sources of information. The purpose of this information seeking is not to control the outcome, but to feel in control by reducing uncertainty and increasing the predictability

of the situation and to manage reactions to the result by anticipatory coping. This type of control, sometimes known as secondary control, is closely allied with the repertoire of other coping responses that people mobilize in an effort to regulate their responses to aversive experiences. It has important uses in medical settings, where the procedures for psychological preparation for surgery and stressful medical procedures have the effect of increasing cognitive control by providing information and helping patients mobilize a range of coping responses. In the self-regulation model of health developed by Leventhal, control is a key dimension in the cognitive representation of health threats, and variations in controllability influence effective adaptation.

People vary in the extent to which they exert effort to establish control over the situations with which they are confronted, and some individuals appear to have a high need for control. This may be maladaptive in some circumstances. Studies of work stress indicate that when high need for control is blocked by low extrinsic rewards (such as poor pay or promotion prospects), the individual may be placed at increased risk for coronary heart disease. People with a high need for control may find it particularly difficult to come to terms with experiences over which they have no control, such as the injury of a family member in a traffic accident.

Control and Well-Being

Control and Aging

Growing old is associated with a diminution of control. When people retire from work, their economic power is reduced, they have less authority than before, and their social networks shrink. Impaired physical health may increase people's sense of vulnerability, while they are exposed more often to uncontrollable events such as the death of contemporaries. A number of studies have documented the links between aging and the loss of control, though there are exceptions. Successful aging, or the maintenance of well-being and effective functioning despite chronological progression, is coupled with maintenance of beliefs in personal control. People may adapt by lowering their valuation of the importance of areas of life over which they lose control and by investing in social relationships more selectively than before. The impact of increasing sense of control and autonomy on the well-being of elderly population has also been investigated. Randomized trials of increased involvement in decision making in institutionalized elderly

groups have demonstrated improvements in mood and activity levels associated with enhanced control.

Control and Pain

The effects on pain of having control over the source of painful stimulation have been studied extensively. These experiments suggest that having behavioral control leads to a reduction in the subjective and physiological impact of the painful stimulus and may also increase pain tolerance. However, the benefits of control depend on the confidence that people have in their response efficacy, so perceptions are again important. It is interesting that the favorable effects of control over acute pain are observed despite the fact that stress-induced analgesia is elicited when there is a lack of control. It is likely that control allows behavioral and cognitive coping methods to be deployed that in turn reduce distress. Brain imaging studies have shown that when pain is perceived to be controllable, there is an attenuation of activation in the anterior cingulate, insular, and secondary somatosensory cortex, areas of the brain that are associated with pain processing. Interestingly, placebo analgesia results in alterations in brain activity in pain-sensitive brain regions, indicating that the control associated with beliefs leads to changes in the experience of pain.

Chronic clinical pain is often accompanied by feelings of helplessness, lack of control, and depression. Some authorities have argued that there may be a progression from feelings of personal helplessness in the early phases of a chronic pain problem to general helplessness (the belief that no one is able to control the pain) in later stages. The impact of chronic pain on well-being is that of a uncontrollable stressor, since by definition a pain that becomes chronic has not been alleviated and so has not been controlled. The generalization of distress about pain to disability and depression mirrors the phenomenon of learned helplessness.

The links between control and pain can be harnessed for patient care. As noted earlier, providing patients with control over sources of potential pain (for example, during dental examinations) can increase tolerance. Patient-controlled analgesia is used in a variety of medical settings with both adults and children and has benefits in terms of both emotional well-being and analgesic use. Several studies have found that when patients can control the level of analgesia, they use less medication than when it is provided by the physician. Rehabilitation programs for patients with chronic pain have a strong element

of increasing perceived control by providing patients with greater and more effective coping options.

Control and Illness

Most serious illnesses bring with them strong feelings of loss of control. When people have heart attacks or are diagnosed with cancer, they feel that they are no longer in control of their bodies, and their future plans are put in jeopardy so that they lose a sense of control over their destiny. Loss of control is often accompanied by other facets of helplessness, including hopelessness, distress, and passivity. Similar patterns occur in chronic health problems. For example, high levels of perceived control over asthma are associated with better self-management skills, reduced risk of hospitalization, and less restricted activity, independent of the severity of asthma itself. Some studies have found that recovery from serious illness such as stroke and major fractures is positively correlated with high internal control beliefs.

Many procedures for improving the emotional state of patients have the effect of enhancing perceived control. Thus, the methods used to prepare women for childbirth increase perceived control by providing a repertoire of coping response. Stress management procedures during cardiac rehabilitation enhanced perceived control and patient self-efficacy by increasing confidence in the resumption of normal activities. A particular area in which the issue of control has been contentious surrounds patient choice. To what extent should patients be involved in medical decision making? A number of studies indicate that although patients desire information about issues surrounding medical decisions, they sometimes prefer to delegate responsibility for the decision itself to the doctor. This should not be too surprising, since it is the typical pattern found in any society with specialist roles. While we might want to know all the facts, we would expect the car mechanic to decide how to fix an engine or the chef to use judgment and skill to prepare the complicated dish we have ordered. Patients often wish to be involved in decision making, particularly when there is a genuine choice of more than one effective alternative, but seldom wish to take authority completely away from the physician.

Conclusions

Control has emerged over recent years as a powerful explanatory variable in stress research. It is relevant

to a wide variety of settings, from basic experimental research on neuroendocrinology and neurochemistry to the experience of people in different socioeconomic sectors of society. There is a danger that such an attractive integrating notion will be misused and employed as a global explanation for completely unrelated phenomena. However, if care is taken not to confuse the different meanings of control, the construct has considerable value in understanding stress.

Introduction

A Life Stress and Illness Model

Discussion

Introduction

Stressful life events can include challenges of high magnitude. However, many life change events occurring in people's lives are of low to moderate intensity and are part of their normal life experience. When do these events of lesser magnitude reach a level at which they can lead to illness? In addition, how is it that some individuals tolerate brutally traumatic life events with only temporary discomfort while others exposed to the same events react with severe and long-lasting disability? To help answer these questions, I have found that the optical lens and photographic filter model presented here can be helpful.

A Life Stress and Illness Model

An early activity that helped in the creation of the optical lens and photographic filter model was a scaling experiment to determine the relative significances of 42 typical life change events. This allowed for quantitative estimates to be made of a person's recent life change events during an arbitrary period of time. Recent life change magnitudes found for large samples of individuals were seen to correlate positively and significantly with their near-future (the following 6 months to 1 year) illness experiences. The original list of events was enlarged in 1975 and rescaled in 1978 and 1995. When comparing the average life change magnitude values over 30 years (1965–1995) the average increase in magnitude was 45%. Thus, life change stress appeared to increase at a rate of 1.5% per year over this 30-year interval.

A model was created using optical lenses and photographic filters to display individuals' exposures to stressful life change events, their perceptions of the significances of these events, their psychological and physiological reactions to these perceptions, their

coping with these reactions, and the possible subsequent illness behaviors leading to diagnosed illnesses. The full six-step model is shown in [Figure 1](#).

Step 1: Perception

In [Figures 1 and 2](#), individuals' recent life change exposure is represented by a series of light rays (lines). The thickness of these light rays indicates the differing life change magnitudes of the events. Thick dark rays represent highly significant events, such as marriage, divorce, and death of a parent. Thinner rays signify less meaningful events, such as a residential move or a purchase of an average-priced automobile.

The influence of perception in altering people's evaluations of their recent life change events is shown in step 1 using a polarizing filter. Just as a polarizing filter diminishes the intensities of some light rays and augments others, the perception of the significance of the recent events may be diminished or augmented according to people's past experiences with similar events and their current social supports. Early life influences, such as intelligence, educational, and social class, can also lead to alterations in their perceptions of life change events. For example, a poorly educated, financially challenged person may perceive the stress of losing his or her job as substantially more of a life change than a highly educated, financially secure individual who has the time and resources to find other employment.

Step 2: Psychological Defenses

Once challenged by significant recent life change events, people quickly employ a variety of psychological defense mechanisms, such as denial, displacement, repression, and reaction formation in an unconscious, almost reflexive, manner. These defenses tend to diffract away the potential impact of these perceived life events on people's psychophysiology. A negative optical lens shows this diffraction for step 2 in the model ([Figure 3](#)).

Some individuals employ their psychological defenses so strongly, and so persistently, that they show nearly complete insulation from the expected psychophysiological responses (in step 3). For example, it has been reported that some patients with myocardial infarction who have been hospitalized in coronary care units are in denial to such a degree that they convince themselves they never had a heart attack. Such strongly defended people have even been shown to develop fewer cardiac arrhythmias and to experience better survival rates than

Figure 1 The lens and filter model.

Figure 2 Step 1.

do more realistically oriented patients in the same coronary care unit.

Although psychological defenses can be extremely helpful in the short term, they often prove to be maladaptive in the long run. To use the coronary patients example once again, their use of one or more psychological defenses may help them survive the first few days after infarction, but these patients

may not eventually learn to deal with the realities of this illness. They may not stop smoking, reduce their body weight, begin a physical fitness program, or learn to control their typical unhelpful psychological responses to life stress.

Step 3: Psychophysiological Responses

The box in Step 3 represents the body's internal milieu where various psycho-physiological processes take place. These responses can be divided into two categories: responses of which people are aware, such as sweating, pain, or muscle tension; and responses that occur outside people's awareness, such as elevated serum cortisol or a rise in blood pressure (BP; see Figure 3).

An example of incompletely defended life stress events might be found in people who have cancer. Such people may experience the psychological responses to recent life stress of helplessness and hopelessness. These psychological responses have been shown to lead to reduced immunological competence, facilitating an exacerbation of this disease.

Figure 3 Steps 2 and 3.

Figure 4 Steps 3 and 4.

Step 4: Response Management

Once individuals become aware of their psychophysiological responses to recent life stress, and especially if these responses are seen as worrisome, these responses are labeled symptoms. People may then decide to employ one or several response management (coping) techniques. For example, individuals may try muscle relaxation, meditation, exercise, or start taking various medications. A color filter is used here in the model to indicate that successful coping can absorb some of the psychophysiological reactions (symptoms) in much the same manner that a color

filter absorbs light rays of certain frequencies (**Figure 4**). Coping in this model is defined as consciously regulated practices and behaviors designed to reduce and, it is hoped, to eliminate symptoms.

Coping, or response management, is a potent resource for dealing with environmental challenges. Because defenses are of short-term effectiveness, coping can achieve more lasting results. To use the cancer patients example once again, after experiencing feelings of helplessness and hopelessness, they may institute behaviors such as seeking medical care, using social supports, and developing their spirituality.

Figure 5 Steps 5 and 6.

These coping activities may help to reduce, or even eliminate, their depressive symptoms. In addition, this coping may also counteract some of the psychophysiological activations that promoted the expression of their cancer in the first place.

Step 5: Illness Behavior

When people's abilities to cope with their environmental challenges are insufficient and their attendant psychophysiological arousal cannot be absorbed, body symptoms are likely to be sustained, leading to tissue breakdown, organ system dysfunction, and disease. A positive lens is pictured in [Figure 5](#) to represent illness behavior. As symptoms of headache and elevated BP continue in the figure, the affected individuals may then decide to seek medical care. It is clear from epidemiological studies that at least as many people with sustained symptoms secondary to poorly managed life stress fail to seek medical care as those who do. Thus, doctors see only a portion of people experiencing mind and body effects of unresolved life stress leading to bodily symptoms and disease.

Step 6: Illness Measure

The final steps in the model ([Figure 5](#)) represents people with long-lasting symptoms progressing to the point of illness who then seek medical consultation and receive one or more diagnoses. The patient's illnesses and their treatments are usually documented subsequently in a medical record.

Many stress and illness studies use medical records as a criterion for defining a case. Thus, people exposed to a significant recent life stress, such as surviving a flood or an earthquake, would only be part

of such a stress and illness study if they followed the entire path displayed in [Figure 1](#) and became a case. People who defended well against and/or coped successfully with the trauma and those who became symptomatic but never reported for medical care would be missed.

Discussion

According to the lens and filter model, people who manage to remain healthy following severe life stress do so by successfully managing steps 1–4. Those who do not handle these four steps effectively are likely to be the ones who develop lasting symptomatology and disease (steps 5 and 6).

Perception, psychological defenses, and coping skills seem to develop early in life. It is extremely beneficial to be endowed with an abundance of biological (genetic) and biographical (acquired) assets. Returned prisoners of war and political hostages who generally stayed healthy during and following captivity often appear to have been born and bred to handle stress well. That is, they had a high number of biological and biographical assets, such as high intelligence, good parenting, ample social skills, and perseverance in adversity, to assist them in managing their perceptions of stress, appropriate use of defenses, and successful coping. Conversely, others who became clinically ill during and following captivity tended to display more negative perceptions of stress, exaggerated and/or prolonged defenses, and restricted coping behaviors – both early in their lives and during and following capture.

Recent application of this model has been found in military men and women returning home from duty in Afghanistan and Iraq. The effective approach to recovery from combat stress is to not tell their war experiences over and over (see **Combat, Acute Reactions to; Combat Reaction, Chronic**). Rather, they should begin to understand the power of their biological and biographical assets and liabilities on their recent stress experiences, see how current life stresses (which they can do something about) add to their current symptoms, and evaluate the effectiveness of their current coping capabilities. Often, an answer to their physical and psychological discomforts can be found in the expansion of their coping repertoires.

Stress and Coping

Chronic Illness

Structured Coping Programs: Learning How to Cope Effectively

Summary

Glossary

<i>Cognitive reappraisal</i>	A form of coping that focuses on changing one's attitudes and beliefs toward a stressful situation.
<i>Coping</i>	Cognitive and behavioral efforts to manage stress.
<i>Emotion-focused coping</i>	Attempts to manage one's emotions during stressful periods.
<i>Problem-focused coping</i>	Attempts to directly change a stressful situation.
<i>Relationship-focused coping</i>	Attempts to manage one's social relationships during stressful periods.

Coping describes cognitive and behavioral responses to a stressful situation. These responses are determined by the interaction between the characteristics of the person and characteristics of the situation. When these responses are particularly effective in reducing strain, due to the expertise with which they are selected and employed, we could say these responses are particularly skillful. When an individual experiences a stressor that threatens to overwhelm current personal resources, such as a chronic illness, an intervention that emphasizes coping skills training can be helpful. However, there is no one coping skill that, once learned, becomes a magic bullet, effective with all kinds of stress. An important part of being a skilled copier is being able to match a stressful situation with the most effective strategy that is appropriate for the given context. Given this, flexibility in coping appears to be a key aspect of effective stress management.

Stress and Coping

Everyone experiences stress at times during his or her life. However, what is extremely stressful to one individual may not be at all stressful to another. How a situation is evaluated, or appraised, is an important determinant of the degree of stress experienced by the individual. Coping is loosely defined as the things we

think and actions we take to ameliorate the negative aspects of a stressful situation. How we manage stress is critical because overwhelming stress can cause psychological distress as well as have both short- and long-term negative consequences for physical health. The ability to cope successfully with a stressful situation depends on a number of factors. Primary among these are the resources one brings to the stressful situation. These resources include one's personality, age, financial assets, education, previous experiences, social support, and physical and mental health. Both resources and subjective appraisals are important determinants of the degree of stress experienced by the individual. If a situation is not appraised as taxing one's resources or ability to cope, it may not be experienced as stress at all. Features of the situation, such as the desirability, controllability, and severity of the stressor, are important in shaping coping responses. Certainly there are many types of stressors that are a tremendous strain for almost any individual.

We review here ways of coping with stress. Reviewing the entire literature on effective and maladaptive coping across a multitude of stressors is beyond the scope of this article. Here we focus primarily on chronic illness, which has been the center of a great deal of research. At some point in their lives, all individuals must cope with chronic illness, either personally or through a significant other. Finally, we review evidence-based coping skills interventions.

Ways of Coping

Problem-focused coping Problem solving is a strategy that quickly comes to mind as an effective way of attempting to remedy a negative situation. Defining the problem, generating alternative solutions, comparing these alternatives in terms of their likely costs and benefits, selecting a likely solution, coming up with a plan, and then acting on it are steps that most of us take when we determine a situation to be one that we can do something about. These strategies primarily involve changing aspects of the situation. Other problem-focused coping strategies may be geared toward changing ourselves, such as learning new skills and procedures, thereby increasing one's coping resources.

Many problem-focused coping strategies that can be enumerated as applicable in specific situations do not generalize broadly across all types of stressors. For example, problem-focused strategies used to cope with chronic pain may not be useful for coping with a pressing deadline at work. Even in situations in which problem-focused strategies could be used to great effect, if the individual perceives the level of threat to be very high, it may be impossible for such

strategies to be employed effectively. Excessive threat has been found to have negative effects on cognitive functioning and on the capacity for information processing. A common example of this often occurs in a physician's office, when patients are given bad news about their health. At such times, patients may have difficulty comprehending any additional information about treatment and prognosis that the physician may wish to convey. This phenomenon is due to a reduction in cognitive functioning brought about by the patient's experience of feelings of threat or harm.

Another important determinant of problem-focused coping is the individual's perception of the situation as one that is amenable to change. In a study of middle-age people coping with stressful encounters, Lazarus and colleagues found that people adapted better to stress when they used more problem-focused coping for an encounter that the person felt could be manipulated. However, if the encounter was judged as one requiring acceptance, more emphasis was put on emotion-focused coping.

Emotion-focused coping The primary goal of emotion-focused coping is to lessen emotional distress. Some of the ways this may be achieved are through avoidance, distancing, and wishful thinking. Another approach may be to minimize the threat of the situation, for example, via cognitive reappraisal. Cognitive reappraisals involve changing the meaning of the situation without changing it objectively. For example, a stressed person may focus on how much worse things could be, perhaps by comparing him- or herself to others less fortunate. Noting how much better one's situation is than the situation of others is called "engaging in downward social comparisons." There are also emotion-focused strategies directed toward diverting attention from the problem, such as engaging in physical exercise, meditating, having a drink, expressing one's anger, or seeking emotional support. Similar to problem-focused coping, a coping response that is helpful in one situation may be harmful in another. For example, denying the severity of chronic heart disease may be beneficial right after diagnosis to alleviate anxiety and anger, but it is problematic during rehabilitation.

Relationship-focused coping Recently, attention has also been directed toward the ways that people attempt to maintain their important social relationships during periods of stress. People in enduring relationships cannot concern themselves only with the situation they are facing, but must also consider the implications for their partner and for the relationship.

This focus on relationships during stressful episodes may be particularly important when a loved one has a chronic illness or disability. For example, O'Brien and DeLongis pointed out the usefulness of empathic coping by caregivers of Alzheimer's patients. Other types of relationship-focused coping involve providing support and attempting to compromise when there is a disagreement. Not all attempts to manage relationships during stressful periods have positive effects. Coyne has found that emotional overinvolvement can have serious negative consequences on the health of family members.

Although some people are more skilled at coping with stress than are others, it is impossible to identify a set of coping strategies that can be called "good" ways of coping. The context in which the stressful situation occurs, the type of problem, the other people involved, and the personality characteristics of the individual are only some of the factors that affect how to best deal with the situation. Further, two people might use identical strategies with different degrees of success, depending on how skillfully the strategy is implemented. However, researchers have pinpointed some general ways of coping that appear to be either adaptive or maladaptive in particular types of situations. A major type of stressor is chronic illness, but differing types of illnesses require different coping skills.

Chronic Illness

Due to medical and technological advances, acute illnesses have given way to increases in chronic illnesses as the primary cause of death in advanced countries. Given the improvements in treatment of chronic illnesses, people who adhere to medical advice can often live relatively normal lives for a long time after diagnosis. It is therefore important to understand how successful adherence and coping with illness can aid in adaptation.

Adherence

Ajzen and Fishbein identified two factors that predict someone's intention to adhere to medical recommendations for a chronic illness, in particular, and to any health behavior, in general. First, a person's attitudes toward the behavior, determined by the extent the person values the outcome of the behavior, predict the person's intentions. Second, this intention is predicted by the perception that important people in the person's life value the behavior and the extent he or she cares about what these people think. Although these factors predict intention well, they fare less well in predicting actual adherence to medical regimens and recommendations for adaptation to chronic

illness. People may intend to perform a health behavior but might not if they are not able or ready.

Adhering to health recommendations is often strikingly low, particularly for lifestyle-change recommendations associated with chronic illness. Rates of adherence are influenced by the experience of side effects, treatment complexity (e.g., one pill a day at dinner versus a handful at different times per day, as in some cases of HIV treatment), the quality and quantity of support received from both the health professionals and important others, and cultural norms. Furthermore, some people avoid recommendations from health professionals and do not adhere to a prescribed regimen, and still others may deny that they are at risk as a way of coping with the stress associated with being ill. These methods of coping may have negative consequences for illness progression. Other people may actively cope by strictly sticking to the medical regimen.

Coping with Chronic Illnesses

When confronted with illness, people's physical and psychological worlds often become disrupted. People with chronic illness face potential mental and physical health problems and disruptions in social functioning. Those with chronic illnesses are challenged by having to alter their self-perception, to integrate the concept of being chronically ill into their lives, and to find meaning in their illness and lives. People who find positive meaning in their illnesses and accept the physical, mental, and social changes that occur with a chronic illness adjust better to illnesses than those who do not. In the following sections, we review four major health problems that impact individuals and thus receive increased attention and research: cancer, chronic heart disease, HIV disease, and chronic pain.

Coping with cancer The question of whether psychological factors, such as coping strategies, affect cancer development has intrigued researchers for years. Some research has suggested that a "fighting spirit," or coping by fighting angrily against the diagnosis, may be associated with living longer with cancer, whereas passively accepting ("stoic acceptance") of the disease and feeling hopeless may predict poorer courses. Under some circumstances, people who minimize or deny the illness's impact on their lives and continue on with daily activities also have longer survival rates. In contrast, repressing negative emotions may be linked with speedier cancer progression. Although the jury is out on whether social support and coping effect initiation, disease course, and mortality rates among cancer patients, research clearly

indicates that how people psychologically cope with the illness and whether support is received affect the psychological well-being, adjustment, and quality of life of cancer patients. The benefits of psychological interventions are apparent in the emotional lives of cancer patients, even though claims of extending patient's lives may be premature.

Coping with Chronic Heart Disease

Reacting to stress with anxiety and anger has been linked to the development of chronic heart disease (CHD), especially in men. In addition, during the first stage of recovery following a heart attack, coping responses that involve denial and that may serve to reduce anxiety and anger toward the illness appear to be more beneficial than are more active coping strategies. During the first stage of the disease, supportive interventions are often most useful. However, after a patient's discharge from a coronary care unit, more active coping strategies are important. For example, interventions that focus on stress management, as well as educational interventions that emphasize lifestyle changes and compliance with medical advice are important in increasing both health and well-being. Good nutrition and exercise are critical factors in preventing CHD as well as in recovery from a heart attack, and many preventive interventions are focused on changing these health-related behaviors.

Coping with human immunodeficiency virus disease The course of human immunodeficiency virus (HIV) disease often begins with an acute, flulike illness, but then remits into an asymptomatic stage that could last between 2 and 10 years. People with HIV may then cycle among (1) chronic infections, (2) symptoms that lead to a diagnosis of acquired immune deficiency syndrome (AIDS), and (3) back into an asymptomatic stage, depending on the effectiveness of the antiretroviral medications and other factors. The risk of continuously cycling through these stages and the fears associated with them may cause severe distress for those affected by HIV.

When people learn of a positive HIV antibody test result, they usually react with increased psychological distress. Blaming oneself for the illness, denying the reality that one has contracted and is living with HIV, and holding onto false hope have been associated with poor psychological adjustment to HIV disease and lower levels of CD4 cells, markers of immune functioning. On the other hand, those who find meaning and who create positive experiences in their lives tend to fare better psychologically. Finally, active coping strategies that promote taking care of one's

health, getting information about the illness, seeking support, and adhering to medication have all been associated with better psychological and physical outcomes for people with HIV.

Psychological interventions for people with HIV disease range from encouraging people to seek out information regarding their illness to helping them weigh the pros and cons of disclosure and drug adherence. Therapists can also help patients plan their drug-adherence schedules and teach them coping skills to deal with potential side effects. As well, psychological interventions may promote psychological adaptation to the illness and help people find meaning in their experience with HIV.

Coping with chronic pain Pain is considered chronic when the symptoms have lasted for a period longer than 6 months. Common types of chronic pain are lower back pain; joint pain as a result of rheumatoid arthritis or osteoarthritis; headaches; pain resulting from chronic illnesses, such as HIV disease and cancer; and various myofascial pain syndromes, usually associated with diffuse musculoskeletal pain. Research has demonstrated that psychosocial factors, such as social support, coping, and patients' beliefs, predict approximately half of the variation of long-term disability resulting from chronic pain.

Most coping efforts are directed toward two main goals: (1) prevention or reduction of pain and (2) maximization of quality of life despite pain. A host of factors, such as the nature of the pain, the expectation of relief, and the specific situation, influences the effectiveness of a particular coping strategy. However, there are consistent findings that point to a relationship between particular classes of coping strategies and the degree of impairment.

Catastrophizing is a cognitive process that includes negative self-statements and excessively negative beliefs about the future. Pain patients may express such things to themselves or to others, saying, "This pain will never go away" or "I can't cope with this pain anymore." Catastrophizing and avoiding activities related to illness-specific exercises and social-leisure activities have been found to be associated with poor outcomes. The diversity of these outcomes is remarkable: increased pain and disability, greater use of the health care system and medication, limited activities, and depressive symptoms in patients with chronic pain.

Probably the most adaptive method of coping with chronic pain involves behaviors or cognitions that divert the person's attention from the pain and toward some more positive experience. Distracting oneself with other activities such as socializing,

reading, and painting reduces emphasis on the experience of pain and has beneficial effects on mood as well. Activities requiring a focus of attention tend to reduce the activation of the sympathetic nervous system, leading to further reductions in pain intensity. Guided relaxation, or transformational imagery techniques, in addition to reducing pain, can also serve to increase feelings of self-efficacy.

Structured Coping Programs: Learning How to Cope Effectively

Coping interventions often focus on learning to appraise stressful contexts more adaptively and then to cope more effectively with the demands of these contexts. In other words, reducing the experience of stressors as threatening and adjusting the sense of control people have over the stressors are key to adaptive coping. We review here three evidence-based coping skills interventions designed for patients with chronic illnesses: coping effectiveness training (CET), cognitive-behavioral therapy (CBT), and mindfulness-based therapies.

Coping Effectiveness Training Program

Folkman, Chesney, and colleagues developed a group-based coping intervention at the Center for AIDS Prevention Studies at the University of California at San Francisco. This intervention follows closely Lazarus's model of stress and coping. The intervention focuses on helping individuals to change their appraisals, improve their coping skills, and obtain beneficial social support when needed. Although this intervention has been tested with HIV-positive men, it is designed to apply to a broad range of stressful contexts and has been applied to various chronic problems, such as spinal cord injury.

First, participants learn to distinguish between global and specific stressful situations. It is much easier to feel in control of a specific stressor (e.g., fears associated with receiving HIV antibody test results) than a vague, complex, global condition (e.g., coping with AIDS more generally). Second, participants learn to distinguish between those aspects of specific stressors that are changeable (e.g., finding ways to spend time while waiting for lab results) and those that are unchangeable (e.g., the lab results per se).

Emotion- and problem-focused coping strategies are then evaluated as possible methods of coping with the unchangeable and changeable situations, respectively. Strategies developed and practiced include cognitively reframing the situation as less stressful, selectively attending to positive aspects and distancing oneself from distressing aspects of the situation,

asking for information, and using humor to diminish the negative impact of the situation. They also consider maladaptive forms of emotion-focused coping, such as smoking, drug use, and overeating, and the resulting negative impact associated with these strategies. Various decision-making strategies are taught, including ways to evaluate the probable outcomes of different approaches to a problem. Participants are also trained in communication skills, such as listening, communicating, and negotiating.

CET also has a component to help people obtain the social support they need from others. Support is considered to be informational, emotional, or tangible, and participants are taught to identify those members of their social network who are most able to provide the specific type of support required and how to best enlist their aid.

Cognitive-Behavioral Therapy

Many people who have a chronic illness or psychological problem see themselves as incapable of changing their situation. CBT directly challenges people to alter the way they think about themselves, the way they behave, and the way they deal with problems and their illnesses. The theoretical underpinning behind these therapies is that cognitions, behaviors, and emotions are intricately interconnected and that altering one affects and alters the other two.

CBT is a structured, evidence-based intervention that combines two effective forms of therapy: behavioral and cognitive therapy. Treatment usually begins with a behavioral component, breaking long-term goals or problems into small steps that can easily be taken by an individual. For example, a person with debilitating chronic back pain who wants to be able to work again may be encouraged to break down the goal into a shorter-term goal, such as being able to go for a 10-min walk again. In such a way, the person is encouraged to drop the overwhelmingly large long-term goal for simpler smaller goals that are manageable and attainable. Asking a patient to engage in activities, such as exercise and social activities, has the added benefit of getting the person active again and challenges the person's thinking that he or she cannot do anything. Accordingly, the person's self-efficacy can be slowly and incrementally heightened.

The cognitive component of CBT aids patients in coming to understand how their patterns of thinking might cause psychological problems. Maladaptive ways of experiencing oneself and situations can cause and enhance the psychological problems associated with mental or physical illness. Therapy and homework are designed to heighten the awareness of behaviors, feelings, and thoughts associated with specific

stressors, situations, or conditions. Then, the person is encouraged to evaluate the pros and cons of his or her attitudes and beliefs regarding the stressor and to offer positive interpretations or cognitive reappraisals of situations with the intention of challenging the negative thought pattern. The patient, therefore, learns to actively seek new ways of perceiving or appraising situations that are less damaging to their psychological and physical well-being.

Mindfulness-Based Therapies

Over the past 2 decades, we have seen growing interest in incorporating mindfulness-based approaches into therapies for such conditions as chronic pain, stress, depression relapses, and CHD, to name a few. The goals of these therapies are to teach people how to manage everyday stress and pain and take responsibility for their well-being. Mindfulness involves moment-by-moment awareness of what a person is experiencing, such as paying close attention to breathing, noises, sensations in the body, inner feelings and thoughts, and our reactions to specific situations. Mindful awareness involves meditation exercises and is often coupled with stretching to help attain a mindful state. The person observes the moment-by-moment sensations, cognitions, and emotions without judging whether they are bad or good, important or trivial, or sick or healthy (nonjudgmental observation). The person is encouraged to recognize and accept his or her limits and body, as opposed to pushing and pulling at his or her physical and psychological limits. The goal is for the person to experience a new relationship with the mental or physical condition instead of doing the same old catastrophizing, avoiding, or other maladaptive coping strategy.

Mindfulness-based approaches have been applied to various physical and emotional problems and have received empirical support. Questions have been raised, however, regarding the methodology employed in studies designed to evaluate the therapies. Others consider mindfulness-based therapies as an alternative to more traditional approaches that involve learning skills that directly manipulate the stressor, negative thoughts, or feelings.

Summary

There are a number of factors that determine whether an individual can cope effectively with a particular stressor. An important first step is to appraise the situation in a positive yet realistic manner. Further, breaking up a global stressor into those aspects that can be changed and those that must be accepted can facilitate the identification of potential coping

strategies. Practicing new coping strategies, considering the possible consequences of several different approaches, and obtaining support from others can result in a reduction in the negative consequences of stress. For those situations that threaten to overwhelm an individual's current resources, coping interventions that provide support, information, and skills training can be effective.

Classic Inactivation of Glucocorticoid Receptor and Mineralocorticoid Receptor Genes

Tissue-Specific Corticosteroid Receptor Genes Inactivation
Modifying Glucocorticoid Receptor and Mineralocorticoid Receptor Gene Dosage in an Organism or Cell Type

Glossary

Additional transgenesis

Adding an extra gene to the mouse genome; often used for the random insertion of a synthetic gene into the mouse genome by injection into a monocellular zygote followed by the selection of a mouse colony carrying the desired gene.

Corticosteroid receptor genes

Genes encoding the glucocorticoid and mineralocorticoid receptors. These receptors are the intracellular receptors for corticosteroid hormones and function as transcription factors in the cell nucleus, controlling the expression of target genes. These genes are similar to those of the receptors for other steroid hormones: androgens, progesterone, and estrogens. All these genes are derived from a common ancestor, and they form the steroid receptor gene subfamily of the nuclear receptor gene family.

Gene targeting

A technique for the modification of a given chromosomal DNA sequence by

Molecular genetics

homologous recombination in cultured mouse embryonic stem cells. Live animals carrying the mutation can be derived from this modified cell line.

The field of biology concerned with studies of the structure and function of genes at the molecular level. The development of reverse genetic tools, facilitating the introduction of the desired modification into the mouse genome has made it possible to investigate the consequences of targeted mutations at the level of a mammal organism.

Null allele

Often used to define a gene allele that cannot lead to the synthesis of gene product, synonym of (–) or knock-out. A major difficulty of gene targeting in mice is to ensure that the gene is indeed invalidated and that no wild-type or modified protein is produced.

Tissue-specific gene inactivation

The deletion of a given gene from the mouse chromosome only in certain cell types, the gene remaining intact throughout the rest of the body. Such deletions are achieved by introducing two 34-bp DNA sequences – the *loxP* sites – on either side of the DNA segment to be deleted. These sites render the modified allele sensitive to Cre recombinase, which, if present in the desired cell type, binds to *loxP* sites and excises the intervening DNA segment from the chromosome. The *loxP* site and Cre recombinase are derived from the P1 bacteriophage.

The adaptation of organisms is based on their ability to respond to environmental variation by adapting their gene transcription profile to meet actual physiological needs. This is well illustrated by the adrenal release of glucocorticoids (GCs) in response to stress. These compounds may act on various tissues, coordinating immune, metabolic, endocrine, and behavioral responses by activating receptors, which, in turn, directly modulate gene transcription. This system is beneficial in healthy organisms, but dysfunctions in this system constitute a severe threat to the health and well-being of the organism. In humans, the dysregulation of the stress response is associated with the development of physiological and behavioral disorders, such as depression, anxiety, memory deficits, and drug dependence.

GCs bind to two related transcription factors, the ubiquitously expressed low-affinity glucocorticoid receptor (GR) and the high-affinity mineralocorticoid receptor (MR), which acts as a bona fide glucocorticoid receptor in a few cell types, such as hippocampal neurons, but is mostly expressed in cells involved in salt-balance control, in which it serves as a mineralocorticoid (aldosterone) receptor. In these cells, the MR is indeed protected from GCs by 11 β -hydroxysteroid dehydrogenase (11 β -HSD2), an enzyme that converts GCs into inactive forms.

The GR and MR genes belong to the nuclear receptor gene family, the members of which have several characteristics in common. The GR and MR proteins contain two highly structured domains: the DNA-binding domain (DBD) and the ligand-binding domain (LBD). In addition, two domains involved in controlling transcription (the activation function, AF, domains) are located in the N-terminal part of the protein and within the LBD. In the absence of ligand, the receptor exists in an inactive state as part of a large cytoplasmic complex. On hormone binding, the activated GR monomer translocates into the nucleus, where it modulates the transcription of target genes by remodeling chromatin and interacting with the basal transcriptional machinery, coactivators, and other transcription factors. The GR may activate or repress gene expression, by binding directly to its cognate response element in the promoter region of target genes and via DNA-binding-independent mechanisms involving other transcription factors (Figure 1). However, due to the wide-ranging effects of GCs, the precise mechanisms underlying the molecular actions of GR and MR and the nature of their cellular targets throughout the body remain largely to be defined with precision.

To address these issues, various animal models have been developed, based on the use of molecular genetic tools established for the precise modification

of the mouse genome. These tools include classic gene inactivation or mutation by homologous recombination in embryonic stem (ES) cells and tissue-specific gene inactivation based on the Cre-*loxP* system, both of which affect the endogenous gene. Other approaches modify gene dosage by adding a transgene to the genome for the constitutive or inducible (tetracycline system) expression of GR or MR. Critical analysis of the phenotypes resulting from these modifications has both confirmed the expected roles of GR and MR and uncovered entirely unexpected functions.

Classic Inactivation of Glucocorticoid Receptor and Mineralocorticoid Receptor Genes

Glucocorticoid Receptor Is Absolutely Required for Survival

Homologous recombination in ES cells has been used to generate various mutations inactivating the GR gene in mice. The resulting phenotypes were somewhat different. The first attempt involved insertion of a DNA cassette within the second exon to prevent the processing of GR mRNA. This approach generated a hypomorphic allele because alternative splicing of the GR gene can lead to the formation of a truncated mRNA encoding an N-terminally truncated GR protein that contains the DBDs and LBDs (allele GR⁻ or GR^{hypo}; Figure 2). A second mutation was then designed to ensure complete gene inactivation. This mutation consisted of a deletion of the third exon (GR^{null} allele), which encodes an essential part of the DBD, and it introduced a frameshift in the open reading frame following the fusion of the second and the fourth exon. This mutation thus ensures that no GR protein isoform containing the DBDs and LBDs can be formed.

GR^{null/null} animals develop to term, but die at birth because they are unable to breathe due to collapsing of the lungs. They present defects in the maturation of several tissues, including a very thin stratum corneum (the outermost layer of the epidermis) and a defect in pancreas organization. GC levels are tightly controlled by an endocrine cascade (see **Hypothalamic-Pituitary-Adrenal**), which is in turn regulated by a negative feedback loop. The absence of GR leads to a profound imbalance in the hypothalamic-pituitary-adrenal (HPA) axis. Corticotropin releasing hormone (CRH), adrenocorticotrophic hormone (ACTH), and GC levels increase. Consistent with the increase in GC levels, the region responsible for GC synthesis – the adrenal cortex – is markedly enlarged and displays tissue disorganization. Surprisingly, adrenal

Figure 1 The glucocorticoid receptor acts by various molecular mechanisms. Due to their lipophilic nature, glucocorticoids can easily cross the cell membrane. Hormone binding to GR induces a change in the conformation of the receptor, leading to its release from an inactivating multiprotein complex and its translocation into the nucleus. The receptor then binds to glucocorticoid response elements (GRE) in DNA, as a dimer, or to negative GRE (nGRE), thereby activating or repressing the transcription of target genes. It can also modulate the activation of gene transcription by other factors, acting as a coactivator of Stat5 – a transcription factor induced by phosphorylation on GH binding to its receptor – or repressing transcription factors such as AP-1, NF- κ B, or some homeoproteins. GR may also act by other modes, interfering with intracellular signaling cascades by stimulating Akt phosphorylation, for example.

chromaffin cell development is not impaired. Differentiated chromaffin cells are scattered throughout the gland, but are no fewer in number in mutant neonates than in wild-type neonates. This unexpected result demonstrates that GR is not essential for the development of this cell type *in vivo*, whereas the contrary is suggested by results obtained in cell culture. However, GR^{null/null} chromaffin cells do not synthesize epinephrine due to a lack of expression of the gene-encoding phenylethanolamine *N*-methyltransferase (PNMT), the enzyme responsible for converting norepinephrine into epinephrine.

Hematopoietic stem cells from GR^{null/null} animals have been used to demonstrate the role of GR activation in stress erythropoiesis. In the absence of GR, cultured erythroblasts proliferate poorly and rapidly differentiate into erythrocytes. *In vivo*, this has important consequences for survival and adaptation. Chimeric adult animals subjected to irradiation and grafted with mutant stem cells such that they carry only GR^{null/null} erythroblasts cannot rapidly reconstitute a normal number of red blood cells after erythrolisis or

bleeding. In hypoxic conditions, similar to conditions at an altitude of 5000 m, they are unable to adapt rapidly by increasing their number of red blood cells.

GR^{hypo/hypo} animals (originally named GR^{-/-}) display a milder phenotype. Unlike GR^{null/null} animals, all of which die at birth, 20% of GR^{hypo/hypo} mice pass this stage, grow normally, and reach adulthood. Several of the phenotypes of GR^{null/null} animals, such as the almost total absence of the stratum corneum and the pancreatic defect, are not observed in GR^{hypo/hypo} mice. The differences between the two mutations presumably result from the presence of residual GR protein isoforms in GR^{hypo/hypo} animals. A third mutation involving the deletion of the alternative exon 1c and exon 2 has been generated (GR^{ko}). No skin or pancreas phenotypes have been reported for GR^{ko/ko} animals. The inactivation strategy, consisting of the deletion of the second exon, is similar to that of the GR^{hypo} allele and may potentially allow the formation of proteins with a DBD. Further investigations are required to understand the differences between GR^{ko/ko} and GR^{null/null} animals.

Figure 2 Schematic representation of the various GR and MR alleles generated in mice by gene targeting. Promoters are represented by black arrows, exons by boxes and *loxP* sites by gray arrows. The position of the *dim* point mutation is indicated by a star.

Inactivation of the Mineralocorticoid Receptor Gene Leads to Type I Pseudohypoaldosteronism

Mineralocorticoid hormone (aldosterone) is a key element in homeostatic sodium balance control, activating MR in the polarized cells of sodium-transporting

epithelia (distal part of the nephron, colon, salivary, and sweat glands). MR is also expressed in neurons, cardiomyocytes, and adipocytes, in which it may be activated by both mineralocorticoids and GCs. The MR gene has been inactivated by replacing the third

exon with the *lacZ* gene in embryonic stem cells. This exon encodes the first zinc finger of the DBD. $MR^{-/-}$ animals develop normally but die approximately 10 days after birth due to a massive loss of renal sodium and water. Mutant animals present major dehydration, with a high hematocrit and hyperkalemia. The renin–angiotensin–aldosterone system (RAAS), which controls salt balance, is strongly induced. These symptoms correspond to exacerbated human type I pseudohypoaldosteronism, due to mutations in the MR (heterozygous) or ENaC genes. In $MR^{-/-}$ animals, the molecular mechanism underlying the major loss of renal sodium remains unclear. Amiloride-sensitive sodium reabsorption rates have been shown to be low, but the levels of ENaC mRNA encoding the amiloride-sensitive epithelial sodium channels remain unchanged, as do the sodium/potassium ATPase mRNA levels.

$MR^{-/-}$ mice may be kept alive by salt supplementation. Animals may survive if they are given daily subcutaneous injections of NaCl solution until weaning and are supplied with oral NaCl thereafter. Adult animals display high levels of renal sodium excretion, hyperkalemia, and persistent activation of the RAAS. These survivors have been used to study other MR functions. MR is strongly expressed in brain structures, such as the hippocampus. In rescued adult $MR^{-/-}$ animals, the dentate gyrus region of the hippocampus is thinner than in control littermates due to lower levels of neurogenesis, resulting in a lower density of granule cells. The absence of MR may be the primary cause of this defect, but higher levels of GR signaling due to higher circulating GC levels may also be involved.

Tissue-Specific Corticosteroid Receptor Genes Inactivation

The early death of mice lacking the GR or the MR gene precludes the study of the functions of these genes in adult physiology or behavior. In addition, the disruption throughout the animal of genes expressed in many different cell types and encoding proteins with highly diverse functions, results in a phenotype reflecting the combined absence of these functions. This phenotype may therefore be difficult to interpret. The ability to inactivate a gene in a single cell type is therefore a major breakthrough and has clear advantages over the disruption of the gene throughout the body. The Cre–*loxP* system has been used to inactivate the GR and MR genes in a tissue-specific manner. This system is based on the use of CRE recombinase, which binds to a 34-bp DNA sequence (*loxP*) and excises any DNA segment flanked by two such sites. Therefore, if a *loxP* site is present on either side of a mouse gene, that gene will be selectively

Figure 3 Principle of tissue-specific gene inactivation using the Cre–*loxP* system. When crossed with transgenic mice expressing the Cre recombinase in the brain (gray circle), the DNA fragment flanked with *loxP* sites in the same orientation (gray arrow) is deleted in this organ. It remains intact in all other cells of the organism.

deleted in cell types expressing the Cre recombinase but will remain intact in the rest of the body (Figure 3). Conditional alleles have been generated by flanking the third exons of the GR and MR genes with two *loxP* sites, through homologous recombination in ES cells. This DNA modification is very small given the overall size of the GR and MR genes (34 bp versus >100 kb), particularly because the neomycin resistance gene, used for ES cell selection, is removed from these targeted alleles. The insertion of *loxP* sites has no effect on the endogenous expression of the genes, but it makes them sensitive to the presence of Cre recombinase. Mice carrying the GR^{loxP} or MR^{loxP} alleles were crossed with transgenic animals expressing Cre recombinase in various tissues, leading to the conversion, in these tissues, of the GR^{loxP} or MR^{loxP} alleles into null alleles. Analyses of mutant mice lacking GR or MR in particular tissues confirmed some known or suspected functions of the receptor and revealed a number of previously unsuspected functions. Using this approach, we were able to dissect *in vivo* some of the roles of GR because we were able to isolate its function in a given cell type from its effects in the rest of the body.

Tissue-Specific Glucocorticoid Receptor Gene Inactivation

Liver-Specific Glucocorticoid Receptor Inactivation Results in Body-Growth Deficiency The GR gene was inactivated in hepatocytes, by expressing the Cre recombinase under the control of transcriptional regulatory elements from both albumin and α -feto-protein genes, leading to early and robust recombination (AlfpCre transgene). These animals were crossed with mice carrying the GR^{loxP} allele. The resulting mutant mice ($GR^{loxP/loxP}$; Tg:AlfpCre) are referred to as $GR^{AlfpCre}$ mice. Surprisingly, mice lacking GR in their hepatocytes are much smaller than control mice. This difference is first observed at 3–4 weeks of age and is more pronounced in males, suggesting a

dysfunction in growth hormone (GH)-dependent postnatal body growth. The defect is not systemic. GC and GH levels are normal, but the GH signaling pathway is not functional in hepatocytes. The binding of GH to its receptor activates the phosphorylation of signal transducer and activator of transcription 5 (Stat5), which in turn stimulates the transcription of GH-regulated genes. Some of these genes encode secreted factors mediating peripheral body growth. In the absence of GR, the expression of GH-regulated target genes controlled by Stat5, such as insulin-like growth factor (IGF-I), Spi2.1, acid labile subunit (ALS), and major urinary protein (MUP), is strongly reduced. This may be accounted for by physical interaction between GR and Stat5, as shown by coimmunoprecipitation and chromatin immunoprecipitation (ChIP) experiments and by GR acting as a coactivator for Stat5-dependent transcription on GH stimulation. This hypothesis is supported by the similar growth phenotype observed in animals lacking Stat5 throughout the body (Stat5^{-/-} animals) and by analyses of gene expression at the genomic scale, which have identified a subset of coregulated genes, including all known GH-regulated genes in the liver. Significantly, in addition to the role for hepatic GR in the control of body growth, this result demonstrates the essential role of the liver for body growth.

GCs were named based on the function of these molecules in the hormonal control of glycemia. They globally promote glycemia by acting on the fat tissue, muscles, pancreas, and liver, where they stimulate glucose synthesis. Glucose homeostasis was studied in GR^{AlfpCre} animals to isolate the effects of GCs on hepatocytes from those on other cell types. Basal glycemia was normal in GR^{AlfpCre} mice. However, in challenging situations, such as prolonged fasting, the induction of gluconeogenesis is impaired due to deficiencies in the induction of enzymes participating in this pathway, such as phosphoenol pyruvate carboxykinase (PEPCK), TAT, and glucose-6-phosphate (G6P). This leads to hypoglycemia in mutant animals, whereas control littermates maintain normal glucose levels. GR^{AlfpCre} mice have also been studied in pathological situations. The contribution of hepatic GR to the hyperglycemia observed in diabetes was assessed by inducing type I diabetes mellitus, by streptozotocin injection, in GR^{AlfpCre} and control animals. Hyperglycemia was less severe in the absence of hepatocytic GR, probably due to the observed defective induction of PEPCK, reducing gluconeogenesis.

GR^{AlfpCre} mice were used by U. Schibler and colleagues to confirm *in vivo* an unexpected role for GCs – their contribution to resetting the circadian clocks in peripheral tissues. In mammals, the circadian system consists of a master pacemaker in the suprachias-

matic nucleus of the hypothalamus and slave clocks in most peripheral cell types. The mechanisms underlying the resetting of these peripheral clocks remain unclear, but GCs seem to play a role. The injection of dexamethasone, a synthetic GC, induces the expression of circadian genes and shifts the circadian phase of peripheral organs. This effect involves GR in peripheral cells, as shown in GR^{AlfpCre} animals, in which a shift is observed after dexamethasone injection in all organs except the liver.

GR gene inactivation in the liver has also been reported in animals carrying a GR allele in which exon 1c and exon 2 are flanked by *loxP* sites and a neomycin resistance selection cassette. On recombination, this allele generates the GR^{ko} allele. Liver-specific mutants were obtained using a different Cre-expressing transgenic mouse line (AlbCre). Defective cell proliferation was observed after partial hepatectomy, but the body growth rate remained normal. This difference may be due to the use of the AlbCre transgene, which gives later recombination than AlfpCre for other *loxP* targets. It may also be due to differences in the GR mutation because removal of exons 1c and 2 is still potentially compatible with the formation of GR proteins with a DBD, as for the GR^{hypo} allele (as already discussed).

The Glucocorticoid Receptor Gene and Pancreas Programming There is considerable evidence to suggest that elevated maternal GC levels may influence embryonic development, with long-term consequences for the metabolism or behavior of the child into adulthood. Maternal food restriction results in a low birth weight and impaired glucose homeostasis in adulthood. This phenomenon may be related to the association between low birth weight and the appearance of cardiovascular diseases, obesity, insulin resistance, and diabetes at adulthood in humans. It has been suggested that maternal GCs may affect embryonic pancreas development because the consequences of maternal food restriction, including a reduction of the β -cell mass in the pancreas, can be blocked by adrenalectomy. In addition, the absence of GR in developing pancreatic cells leads to an increase in β -cell mass that persists into adulthood. This model was developed using a recombinase transgene expressed under the control of the pdx promoter (GR^{PdxCre} animals). Further studies on these animals should make it possible to analyze the role of pancreatic GR in adult animal metabolism.

The Glucocorticoid Receptor Gene and Mammary Glands GCs are known to influence mammary gland function *in vivo* and to stimulate milk-protein gene expression in cell culture. Mice deprived of GR

in their mammary epithelial cells were obtained using a Cre recombinase transgene expressed under the control of the whey acidic protein (WAP) gene promoter (GR^{WAPiCre}). They produce and secrete milk and nurse their litters until weaning, suggesting that GCs do not act on the mammary gland via GR or that they act on other cells than those secreting WAP. The absence of GR reduces cell proliferation, retarding lobulo-alveolar development.

The Glucocorticoid Receptor Gene and T Cells GCs act as potent anti-inflammatory and immunosuppressive therapeutic agents. The endogenous production of these hormones is involved in the optimization of the immune repertoire during thymocyte maturation and in downregulating the immune response in mature T cells. The role of GR in T cells from animals carrying the GR^{ko} allele was studied by grafting hematopoietic stem cells from fetal GR^{ko/ko} mouse liver into irradiated animals and using the lckCre transgenic line to invalidate the GR^{loxPneo} allele in thymocytes (TGRKO). Analyses of these animal models demonstrated that GR is not required for T-cell development.

In vivo, GR^{ko/ko} thymocytes are resistant to apoptosis induced by stimulation of the T-cell receptor (TCR). This is not a cell-autonomous property of GR^{ko/ko} thymocytes because these cells display normal sensitivity *in vitro*, demonstrating that the evoked GC release on TCR stimulation is involved in this response. TCR stimulation in TGRKO animals is associated with a high mortality rate, probably due to the uncontrolled induction of cyclooxygenase-2 (COX-2) because the selective inhibition of this enzyme prevents the death of mutant mice.

Inactivation of the Glucocorticoid Receptor Gene in the Brain GCs affect many aspects of brain physiology, in addition to repressing the HPA axis by controlling the CRH and vasopressin expression in the neurons of the hypothalamic paraventricular nuclei. In response to stress, these hormones modulate the activity of several neurotransmitter systems and affect behavior. In healthy animals, this response helps the organism to adapt to its environment, but dysfunctions in this mechanism may be associated with the development of behavioral disorders.

GCs can affect neuronal activity and neurotransmitter release, modify cellular shape by remodeling dendritic formations, compromise neuronal survival, and reduce the rate of renewal of granule cells in the dentate gyrus by downregulating neurogenesis.

The GR gene was inactivated in the brain by crossing mice carrying the GR^{loxP} allele with transgenic animals expressing Cre recombinase in neuronal

precursor cells under the control of the rat nestin promoter and a neuron-specific enhancer (the NesCre transgenic line). GR^{NesCre} mice, which have no GR in their neurons and glial cells, survive to adulthood. Because the GR-mediated negative feedback on the HPA axis is disrupted at the hypothalamic level in mutant mice, GC levels are 15 times higher than in control animals. The negative feedback loop continues to function in the pituitary gland (in which the GR gene is not inactivated), but this is clearly not sufficient to control hormone levels. The level of CRH production is very high in the hypothalamus of mutant animals, whereas vasopressin levels are unaffected. The increase in CRH levels induces ACTH production in the pituitary gland, and both mRNA and intracellular protein levels are high. Surprisingly, circulating ACTH levels are significantly reduced. This demonstrates that high GC levels are not sufficient to repress ACTH expression completely but are sufficient to repress ACTH secretion. The mechanisms responsible for higher levels of GC secretion in the presence of lower circulating ACTH circulating levels remain to be elucidated. A similar divergence between ACTH and GC levels is observed in other animal models and in some pathological situations, such as major depression. The high GC levels in GR^{NesCre} mice may have an effect on peripheral organs expressing GR, leading to symptoms reminiscent to those observed in patients with Cushing's syndrome (due to high GC levels), such as a reduced size, low bone density, and changes in fat distribution. GR^{NesCre} animals present a decreased food intake and a reduced metabolic efficiency. In GR^{NesCre} animals, GC levels cycle with a circadian rhythm and are further increased in response to stress.

In the brain of mutant mice, stress-released GCs are not perceived by GR that is absent. We therefore studied behaviors influenced by stress responses in GR^{NesCre} mice to distinguish between those involving GR activation in the brain and those involving other mechanisms. Mutant mice display lower levels of anxiety in the elevated zero maze and the dark-light box, two tasks based on a behavioral conflict between exploring and avoiding an aversive compartment. Despair or depression-like behavior, measured in the forced swim test, was also reduced in the absence of GR. CRH is often considered to be the anxiogenic mediator of the HPA axis. Interestingly, the fact that CRH expression is strongly induced in the hypothalamus of mutant animals, but unaffected in the amygdala, suggests that changes in CRH are not responsible for changes in the level of anxiety of GR^{NesCre} mice. This indicates that central GR may be directly involved in anxiety modulation. A more restricted deletion of the GR^{loxPneo} allele, using a

recombinase expressed in most forebrain neurons (FBGRKO mice), also affects emotional behavior. Despair behavior is more marked, but anxiety levels are reduced, in these mutants in the dark/light box and elevated plus-maze behavioral tasks. This difference between GR^{NesCre} and FBGRKO mice may reflect the restriction of the GR mutation to a neuronal subpopulation in FBGRKO mice. This mutation leads to an increase in GC levels that, in turn, may act on GR-positive neurons. More work is required to define the nature of the neuronal cells in which GR activation modulates particular types of behavior.

The absence of brain GR in GR^{NesCre} mice also has a weak effect on learning and memory retention in a water-maze task designed to test spatial memory. Learning is similar between mutant and control littermates, but retention is slightly affected in mutant mice. Further training sessions, however, overcame this memory impairment, indicating that GR is not essential for the formation of explicit memory.

Addiction is favored by stress responses. Physical and psychological stressors facilitate drug addiction in rodents. The acquisition of drug self-administration, its intensity, and the reinstatement of drug taking even after prolonged periods of withdrawal are facilitated or increased by stress. Even in the absence of stress, GR gene inactivation in GR^{NesCre} mice profoundly reduces the motivation for cocaine-induced self-administration, a test considered to be the best experimental model of drug abuse. In addition, cocaine-induced behavioral sensitization, a process implicated in the development of addiction and defining the increase in the behavioral effects of cocaine observed over repeated drug injections, is abolished in these mice. The molecular mechanisms underlying these effects are unknown, but the absence of GR leads to strong downregulation of the mitogen-activated protein kinase (MAPK) pathway responsible for impaired expression of the immediate early gene *Zif268* (also named *Egr-1*, *NGFI-A*, or *Krox24*). This is particularly evident in hippocampus GR^{NesCre} animals. The MAPK pathway and *Zif268* expression in the hippocampus of control animals are induced by immobilization – an acute stress for mice – but this induction is defective in GR^{NesCre} animals.

Tissue-Specific Mineralocorticoid Receptor Gene Inactivation

In the brain, MR is abundantly expressed in the hippocampus, where it serves as a high-affinity GR. Conditional MR gene inactivation was recently achieved by flanking the third exon with two *loxP* sites (MR^{fllox} allele) and using a transgenic line expressing Cre recombinase throughout the forebrain,

under the control of the CamKII α gene on a bacterial artificial chromosome. The absence of MR does not affect the circadian rhythm or stress response of the HPA axis. MR^{CamKCre} mice have a learning deficit in spatial navigation, as shown in a water-maze task, but display normal retention once the task is learned. MR^{CamKCre} mice also display working memory impairment, as assessed in a radial maze. In contrast to what has been observed in GR mutant animals, anxiety is not affected by the mutation. Significantly, studies on MR^{CamKCre} mice recently demonstrated that MR is responsible for certain rapid effects of GCs on hippocampal signaling that do not involve gene expression.

Function-Selective Glucocorticoid Receptor Mutation

GR acts via different molecular mechanisms involving specific protein–protein interactions, with itself or with other factors, to control gene expression (Figure 1). If these different interactions engage different protein interfaces, it should be possible to define mutations that selectively abolish a given mechanism without affecting the others. This is the case for a mutation in the D-loop region of the DBD that results in the replacement of alanine 458 by a threonine residue (GR^{dim}). This mutation affects the cooperative binding of GR homodimers to glucocorticoid-response elements (GREs), resulting in reduced occupancy of these binding sites. Interactions with other known proteins are not affected. Following its introduction into the mouse genome by homologous recombination in embryonic stem cells, this mutation was indeed shown to reduce the expression of genes known to be controlled via binding to GREs, such as the TAT gene in the liver. In contrast, the GR^{dim} protein is still able to repress the activating enhancer binding protein (AP-1)-dependent expression of the collagenase-3 (MMP-13) and stromelysin-1 (MMP-3) genes and pro-inflammatory NF κ B activity and to activate the expression of Stat5-dependent genes in the liver. Surprisingly, all homozygous mutant mice survived to adulthood. The fact that GR^{null/null} mice die shortly after birth, whereas GR^{dim/dim} mice do not, indicates that the interaction of GR with other proteins is more important for survival than its ability to bind DNA cooperatively on GRE target sites. In adult mice, various phenotypes have implicated defects in GR binding to GREs. CRH synthesis and ACTH release are not impaired in these mice. In contrast, transcription of the *POMC* gene (encoding ACTH) is upregulated in corticotropic cells and therefore requires the binding of GR dimers to DNA. In the hippocampus, dimerization and cooperative DNA

binding seem to be involved in neuronal activity. GR activation in GR^{dim/dim} mice does not lead to increases in calcium currents or in the response to serotonin as in wild-type mice, indicating that dimerization is required for these responses.

Modifying Glucocorticoid Receptor and Mineralocorticoid Receptor Gene Dosage in an Organism or Cell Type

We have so far discussed studies aiming to define the function of the GR and MR genes by means of gene mutation abolishing expression or generating modified protein. The function of corticosteroid receptors has also been studied using approaches that increase or decrease the levels of the corresponding gene products. GR gene dosage has been increased by introducing two additional copies of the receptor gene into the mouse genome using yeast artificial chromosomes. As the entire GR gene, including all the regulatory elements responsible for gene transcription, is present in the 290-kb yeast artificial chromosomes (YAC) used, the expression of the GR transgene should mimic the endogenous expression profile. These animals have a downregulated HPA axis under basal conditions and after acute stress, and they display increased resistance to lipopolysaccharide-induced endotoxic shock. A behavioral analysis of this animal model showed lower levels of despair behavior, with a decrease in GR dosage (GR^{null/wt} animals) giving the opposite response.

Mice over- or underexpressing GR in a given tissue have also been established by additional transgenesis. The first mice with impaired GR function were generated by overexpressing an antisense RNA directed against the 3' prime untranslated region of the GR mRNA. This mouse model has been of great value for studying GR function, but it is problematic for several reasons. The main problem is that it is difficult to determine the actual levels of GR protein in a given cell because transgene expression varies as a function of cell type. In addition, the antisense RNA is expressed ectopically in organs outside the nervous system, probably due to positional effects relating to the use of the human neurofilament promoter. On average, GR levels were 50% lower than normal in the brain, resulting in changes to HPA axis regulation and stress-related behavior and in changes in energy balance and lipid metabolism. GR has been overexpressed in various tissues, including the pancreas, brain, and T cells, using tissue-specific promoters or the tetracycline inducible system.

MR function has also been investigated by means of conditional downregulation and overexpression

strategies based on the tetracycline system. This approach revealed unexpected roles for MR in cardiac tissue. The heart-specific expression of an antisense mRNA directed against MR causes severe heart failure and cardiac fibrosis in the absence of hypertension or hyperaldosteronism, leading to massive water retention. In adult mice, this phenotype was fully reversed within a few days following the abolition of mRNA expression. Mice with conditional heart-specific MR overexpression in the heart also present a cardiac phenotype with marked arrhythmia and high early mortality rates, as observed in arrhythmia-related sudden death in humans.

The different animal models presented here are invaluable tools for the study of corticosteroid receptor gene function. They allowed us to define more precisely the known or expected corticosteroid receptor function, such as, the GR's roles in the HPA axis negative feedback loop and in glucose homeostasis and its functions in immunosuppression and anti-inflammation and the MR's role in the control of the body salt balance. These animal models also clarified the role of GR in the modulation of stress-related behaviors and revealed unexpected roles such as the requirement of GR for GH signaling in hepatocytes. The results are still fragmented, but further analysis of the existing models and of new models targeting other tissues should allow a more integrated understanding of corticosteroid receptor gene functions at the level of the organism. They should also allow us to distinguish in these functions the ones relevant for hormonal control and stress response from the ones that are not associated with the binding of corticosteroids. It is indeed now clear that, in some situations, steroid receptors may be activated by other means than ligand binding, such as phosphorylation. The generation of precisely modified animal models is fastidious and will undoubtedly benefit from complementary approaches, such as the use of short interfering RNA (siRNA) or small molecules that will facilitate combinatorial studies targeting several genes simultaneously.

Acknowledgments

I thank Monique Lazar and Christoph Kellendonk for their critical reading of this review and all the members of the Molecular Genetics, Neurophysiology and Behavior laboratory for our stimulating discussions. I also thank Günther Schütz for his support and for having introduced me to this research field. The work in the CNRS UMR7148 unit is supported by the CNRS, the NRJ foundation, the MILDT, the FRM, the French Ministry of Research (ACI and ANR programs), and the European Union (EAR-NEST consortium).

Corticosteroid Receptor Properties
Cellular Effects of Corticosteroid Hormone Activation
Behavior and the Stress Response
Corticosteroid Receptors in Pathology

Glossary

Adrenalectomy The surgical removal of the adrenal glands from the body.

Corticosteroid hormones Hormones synthesized and secreted from the adrenal gland in response to stress

and also during the diurnal rhythm. The main endogenous glucocorticoids are corticosterone (in rodents) and cortisol (in humans).

Corticosteroid receptors

Intracellular receptor molecules for corticosteroid hormones. On hormone binding, they function as transcription factors in the nucleus of the cell to change mRNA and protein synthesis of target genes. There are two types: mineralocorticoid receptors and glucocorticoid receptors.

Hypothalamic-pituitary-adrenal (HPA) axis

The brain-controlled activation pathway for the secretion of corticosteroid hormones after stress through a hormonal cascade, involving the release of corticotropin releasing hormone from the paraventricular nucleus of the hypothalamus in the brain and adrenocorticotrophic hormone from the pituitary gland.

Hippocampus

A cortical brain structure involved in declarative and spatial memory and the cognitive aspects of emotions, with high

expression of both types of corticosteroid receptors.

Stress A state caused by a real or perceived challenge to homeostasis, which is accompanied by a hormonal stress response.

The effects of cortisol and corticosterone (CORT), the main glucocorticoid hormones in primates and rodents, respectively, are mediated by two types of intracellular receptor molecules: glucocorticoid receptors (GRs, or type II receptors) and mineralocorticoid receptors (MRs, or type I receptors). In peripheral tissues, CORT acts almost exclusively via GRs to affect energy stores, bone metabolism, and inflammatory and immune responses. MRs in epithelial cell types, as present in kidney and colon, are protected from endogenous CORT by the enzyme 11 β -OH-steroid dehydrogenase (11 β -HSD) so that aldosterone may bind to regulate the sodium balance in the body. In nonepithelial targets, such as the brain, both MRs and GRs function as receptors for CORT to act in either synergy or antagonism. GRs and MRs are members of the steroid hormone receptor superfamily and, accordingly, act as transcription factors to change the expression levels of target genes. These genomic effects have a relatively slow onset and long duration. However, CORT may also acutely affect the activity of neuronal cells via non-genomic mechanisms involving MR and possibly GR. However, no such receptors have been identified in mammals to date. MRs and GRs have different pharmacological properties and distributions in the brain. Corticosteroid receptors in the brain and pituitary play a crucial role in the regulation of the stress response and in mediating the effects of CORT on mood and cognition.

Corticosteroid Receptor Properties

Activation of Corticosteroid Receptors

The lipophilic CORT diffuses readily through the plasma membrane of cells to bind to its receptors. Corticosteroid receptors are part of a cytoplasmic multiprotein complex that consists of one receptor

molecule and several heat shock proteins (HSPs). The binding of CORT leads to a rapid chain of events that consists of the dissociation of the HSP, multiple phosphorylation steps, and increased affinity of the ligand-activated receptor for nuclear domains: the Ligand-receptor complex translocates to the cell nucleus to exert its action on gene expression and protein synthesis (Tables 1 and 2).

An important determinant of corticosteroid receptor activation is access of the ligand to the receptor, which depends on several factors in addition to the total plasma concentration of CORT. First, the circulating hormone is bound to corticosteroid-binding protein (CBG)/transcortin and with a much lower affinity to serum albumin. Of the average CORT concentration circulating during a 24-h period in the rat, less than 5% is not bound to CBG, (i.e., is free and biologically available).

Second, the enzyme 11 β -HSD type 2 converts cortisol and CORT to their inactive 11-dehydro metabolites in mineralocorticoid target tissues. Conversely, the 11 β -HSD type 1 isoform, which is often colocalized with GRs, can catalyze the reverse reaction and generate cortisol from cortisone within a target cell. This reaction takes place in the liver and fat cells, and it may also be relevant for certain areas in the brain.

A third determinant of access, which particularly pertains to synthetic glucocorticoids, is the *mdr1a* P-glycoprotein. This protein is expressed in the apical membranes of endothelial cells of the blood-brain barrier. *mdr1a* P-glycoprotein functions as an energy-dependent pump that limits access to the brain of xenobiotic agents, including synthetic steroids. Accordingly, the brain (but not the pituitary) is resistant to the penetration of moderate amounts of dexamethasone.

Corticosteroid Receptor Diversity in Pituitary and Brain

Although the GRs and MRs act as high-affinity receptors for CORT in the brain, these receptor types differ significantly with respect to their pharmacology, distribution, and physiological effects.

Table 1 Characteristics of the two corticosteroid receptor types

	Affinity	Agonists	Antagonists	Distribution
Mineralocorticoid receptor (type 1)	High affinity for cortisol and corticosterone ($K_d \approx 0.5$ nM)	Aldosterone (epithelial cell types as in kidney), cortisol (brain)	Spironolactone, RU 28328	Limited distribution in periphery (kidney, colon, lymphocytes) and brain (limbic brain)
Glucocorticoid receptor (type 2)	Lower affinity for cortisol and corticosterone ($K_d \approx 5.0$ nM)	Cortisol, dexamethasone, RU 28362	RU 38486	Ubiquitous expression in periphery and brain

Table 2 Milestones in brain corticosteroid receptor research

Year	Milestone
1968	First report on selective retention of [³ H]corticosterone in hippocampus
1975	Low retention of [³ H]dexamethasone in hippocampus; high in pituitary
1980	Selective MR agonists discriminate between MRs and GRs
1982	<i>In vitro</i> hippocampus and kidney cytosol contain MRs and GRs
1983	GR acts as transcription factor through DNA binding
1985	MR and not GR retains [³ H]corticosterone in hippocampus
1985	Cloning of GR
1985	First brain map of immunoreactive GR neurons
1987	Cloning of MR
1988	11 β -HSD confers aldosterone specificity to MR
1990	Transrepression of AP-1-induced transcription via GR
1991	First brain map of immunoreactive MR neurons
1993	Differential effects of MR and GR on transrepression
1994	<i>In vitro</i> demonstration of MR/GR heterodimers
1994	Mechanistic differentiation between transactivation and transrepression GR
1995	mdr1a Pgp in blood–brain barrier hampers brain entry of dexamethasone
1995	GR knockout mice
1996	Colocalized immunoreactive MR/GR clusters in hippocampal neuronal nuclei
1998	Knock-in mice that express a dimerization-impaired mutant of GR
2005	Non-genomic effects in hippocampus via MR

Structure The human GR gene is localized on chromosome 5, whereas the MR gene is localized on chromosome 4, indicating an early duplication of their common ancestor during evolution. Despite this early divergence, their genomic organization is very similar, notwithstanding differences at the 5' and 3' ends. The overall structure of GR and MR proteins follows that of the other members of the steroid hormone receptor family. The molecules are generally viewed as consisting of three domains: a highly conserved DNA-binding domain (95% homology between the MR and the GR), flanked by the C-terminal ligand-binding domain (60%), and a large N-terminal domain that contains a transactivation function and is highly variable between the MR and the GR (15%) and among species.

Pharmacology Although GRs and MRs are high-affinity receptors for CORT, they differ in their affinities for several ligands. In the case of cortisol and CORT, an MR has an approximately 10-fold higher affinity than a GR. The important consequence of this is that GRs and MRs are occupied differentially during the day and during stress responses. MRs

are already occupied extensively under basal trough conditions, whereas the saturation of GRs requires hormone levels that occur after stress or after the circadian peak. Because of the high, almost tonic, occupation of MRs, it has been hypothesized that the amount of bioactive receptor protein is an important level of regulation for MRs, whereas the GR signal depends primarily on ligand concentration. Synthetic glucocorticoids have higher affinity for GRs than for MRs, but their access to the brain GRs is hampered by the mdr1a gene-encoded P-glycoprotein.

Distribution GRs are expressed ubiquitously in many different tissues and cell types. In tissues such as the liver, lung, and adrenal medulla, GRs are crucial for appropriate development. MRs have a much more limited distribution, and as receptors for CORT (as opposed to mineralocorticoids), they have been characterized in the brain and some lymphoid tissues. The pituitary, outside the blood–brain barrier, contains GRs as well as MRs, although no specific function for MRs has been described for any of its cell types.

Throughout the brain, immunocytochemical and *in situ* hybridization procedures have shown a widespread distribution of GRs in neurons and glial cells. Particularly high GR concentrations are found in the limbic system (hippocampus, with relatively low concentrations in the CA3 region; septum; and amygdala), in the parvocellular neurons of the paraventricular nucleus (PVN) of the hypothalamus, and in the supraoptic nucleus. In the PVN, the biosynthesis and release of parvocellular vasopressin, corticotropin releasing hormone (CRH), and other neuropeptides are under glucocorticoid control. GRs are also present in relatively high concentrations in the ascending monoaminergic neurons of the brain stem. Moderate GR levels are also found in many thalamic nuclei and in patchlike distribution in the striatal areas, as well as throughout the cortical hemispheres (see [Figure 1](#)).

In the brain, MRs have a more restricted topography than GRs. High MR densities have been found in the neurons of the hippocampal formation, lateral septum, medial and central amygdala, olfactory nucleus, layer II of the cortex, and in brain-stem sensory and motor neurons. This distribution of MRs is essentially the same as that discovered in 1968 by McEwen with the cell-nuclear retention of radioligand after the administration of tracer doses of [³H]-corticosterone to adrenalectomized rats. Aldosterone-preferring MRs involved in salt homeostasis are localized in the anterior hypothalamus and circumventricular organs, such as the choroid plexus.

Figure 1 Distribution of MRs (black circles) and GRs (grey circles) in the rat brain. a, Basal corticosterone secretion; b, Peak corticosterone secretion. MR expression is more restricted and especially high in the hippocampus; the MRs are substantially occupied by corticosterone under basal conditions (i.e., at the circadian trough under nonstressed conditions). The GRs show a widespread distribution and are only partially occupied under basal conditions; they become more fully activated at the circadian peak of corticosterone secretion or after stress. Reprinted from M. Joëls and E. R. De Kloet (1992), Control of neuronal excitability by corticosteroid hormones. *Trends in Neuroscience* 15, 25–30. Used with permission.

The subcellular localization of MRs and GRs was studied in hippocampal neurons by dual labeling immunocytochemistry and confocal microscopy. It was observed that MRs and GRs are distributed non-homogeneously over the nucleus. Both receptors are concentrated in approximately 1000 clusters scattered throughout the nucleoplasm. Many clusters contain exclusively either MRs or GRs, although a significant number of domains were found to contain both receptor types. The latter clusters are candidate sites where the two receptors could interact to establish a coordinated regulation of gene expression. This implies that GR and MR homodimers, as well as the possible MR–GR heterodimers, are associated with distinct nuclear domains.

Corticosteroid Receptor Variants Alternative splicing of the 3' end of the human GR pre-mRNA creates an hGR β variant in addition to the common hGR α variant. However, it should be noted that rodent GR pre-mRNA lacks this splice site and GR β cannot be detected in rodent tissue. The translation of GR α and GR β mRNA produces two proteins that are almost

identical but that differ in their C-terminals, which implies that GR α binds cortisol, whereas GR β does not. However, *in vitro* experiments suggest that GR β is capable of binding to glucocorticoid-responsive elements (GREs) and can form homodimers as well as heterodimers with GR α . Accordingly, GR β has been shown to block GR-mediated transactivation *in vitro*, whereas it does not seem to interfere with transrepression. In the human brain, GR β mRNA is found in the hypothalamus and the hippocampus, but the relative abundance is subject to debate and may be only 1% relative to GR α . Thus, validation of the possible role of GR β as a dominant-negative factor awaits further studies. Different forms of GR may also arise from the use of alternative translation start sites for its mRNA, adding yet another level of complexity to the receptor diversity.

The expression of the human MR gene may result in the formation of at least four transcripts, which are derived from two different promoters. The two main transcripts, MR α and MR β , differ only in the 5' untranslated exon 1 and thus are translated into the same 985-amino-acid MR protein. In rats, an MR transcript derived from exon 1 is detectable in very low amounts. Other intriguing splice variants have been described, including transcripts that code for truncated proteins. The use of an alternative splice site between exon 3 and 4 creates a 12-bp insertion, which, after translation, corresponds to four additional amino acids in the amino acid sequence bridging the two zinc finger domains of the DNA-binding domain. The functional analysis and relevance of these MR variants await further studies.

Variations in MRs and GRs in the form of single nucleotide polymorphism are quite frequent in the normal human populations. Although the biology of these variants is poorly understood, some of these variant receptors can be associated with the metabolic profile, stress responsiveness, and even life span.

Receptor variants may play an important role in disease states. Thus, individuals with familial glucocorticoid resistance may express a GR variant and, as a consequence, have deficient GR function and impaired glucocorticoid feedback resulting in hypercorticism. However, they lack the symptoms of Cushing's syndrome because adrenocorticotrophic hormone (ACTH) and cortisol levels are also at a higher set point and GRs are, in general, less sensitive to glucocorticoid activation. The symptomatology of familial glucocorticoid resistance is usually related to the overproduction of adrenal mineralocorticoids and androgens in response to ACTH. Although these severe inherited deficits in GRs, resulting in asymptomatic hypercorticism, are rare disorders

in humans, there are also pronounced species differences in guinea pigs, prairie voles, and New World monkeys. These animals display a normal circadian rhythm in HPA axis activity, but ACTH and cortisol are circulating at a much higher level. Apparently, the elevated set point in HPA axis regulation is an adequate adaptation.

Regulation of Transcription through Corticosteroid Receptors

As members of the steroid hormone receptor superfamily, ligand-activated GRs and MRs exert their effects by acting as transcription factors to up- or downregulate protein and peptide levels in the cell. MRs and GRs may stimulate or repress transcription by several mechanisms (see Figure 2).

Transactivation via Glucocorticoid-Responsive Elements GRs and MRs contain a nearly identical DNA-binding domain that recognizes specific DNA elements in the regulatory regions of genes: glucocorticoid response elements (GREs; consensus sequence: GGTACAnnnTGtT/cCT). The steroid receptors bind as homodimers and perhaps also as heterodimers to GREs to stimulate transcription. In general, GRs are more potent activators of transcription than MRs, at least in *in vitro* conditions. Heterodimers of MRs and GRs have been shown in cell systems to have, at times, characteristics that are different from either type of homodimer. The strong synergizing effect of GR-activated transcription on multiple GREs is not observed with MR activation, probably due to the

limited homology of the N-terminal sequences. Tyrosine amino transferase and phenylethanolamine-N-methyltransferase (PNMT) are examples of genes that are regulated via GREs.

Repression via Negative Glucocorticoid-Responsive Elements GRs (and possibly MRs) can also repress gene transcription by binding to DNA. DNA elements that are involved are known as negative GREs (nGREs). The sequence of nGREs can be highly variable and differs from the consensus sequence for positively acting GREs. The mechanism by which transcription is repressed also differs between cases. One mechanism involves the binding of GRs to the nGRE to occlude adjacent or overlapping binding sites on the DNA for positively acting transcription factors. An nGRE has been described for the human POMC gene.

Repression via Protein-Protein Interactions The mode of action generally referred to as transrepression involves the repression by GRs of gene transcription activated by other transcription factors, such as activating protein (AP)-1, nuclear factor (NF)- κ B, and cAMP response element binding protein (CREB). GRs interfere with these other factors via protein-protein interactions. This may happen independently of the binding of GRs to the DNA, and dimerization of GRs is not required. The target genes involved lacked GREs.

Corticosteroid receptors may also activate genes in synergy with other, nonreceptor transcription factors.

Figure 2 Three molecular mechanisms of regulation of gene expression. (1) GRs and MRs bind as homo- and heterodimers to GRE sequences to stimulate transcription. (2) GRs (and possibly MRs) bind to negative GRE sequences that diverge from consensus GRE. Through mechanisms such as occlusion of adjacent sites they repress transcription. (3) GRs and MRs interfere through protein-protein interactions with other transcription factors (TFs) at times independent of binding of the steroid receptors to the DNA. This results in antagonism of the effects of the TF (e.g., AP-1 or NF- κ B).

On elements known as composite GREs (cGREs), GRs bind to the DNA in close proximity to another transcription factor and may either repress or enhance the effect of this other factor. In the case of the proliferin cGRE, the GR enhances the effect of the adjacently bound transcription factor AP-1 greatly if the latter consists of c-jun–c-jun homodimers. In contrast, GR binding leads to repression of the action of c-jun–c-fos heterodimers. Interactions with other transcription factors depend by definition on the presence of these factors, which can be regulated by extracellular signals other than steroid hormones. This demonstrates that the effects of CORT vary widely and are context-dependent.

Dissociation between MR- and GR-mediated events may arise through these cross-talk mechanisms because it has been shown that GRs suppresses AP-1 activity under conditions in which an MR is ineffective. It is probable that the unique N-terminal regions of the GR and the MR account for the different properties with respect to transrepression.

Cellular Effects of Corticosteroid Hormone Activation

The activation of intracellular corticosteroid receptors in many cell types may induce a variety of cellular responses, influencing diverse processes such as cellular structure, energy metabolism, or signal transduction. Changes in cellular structure usually develop over the course of several days, whereas effects on energy metabolism or signal transduction may already become apparent within an hour. In peripheral tissues, the activation of GRs leads to pronounced cellular effects, for example, apoptosis of thymocytes (via antagonism of NF- κ B activity) and induction of gluconeogenesis in hepatocytes (through induction of critical enzymes). Here, focus lies on the effects of the MRs and GRs in the brain because these are important factors in the regulation of the HPA axis and of adaptation to stress in general. Although the delayed onset of the observed effects – as opposed to the rapidly induced effects by neurosteroids – favors gene-mediated effects via MRs and GRs, the molecular mechanism has, in many cases, not been resolved.

Differential Effects at the Level of a Single Structure: Mineralocorticoid and Glucocorticoid Receptors in the Hippocampus

The principal cell types in the hippocampus, a brain structure involved in declarative memory processes and (possibly) mood, express both MRs and GRs. The effects of differential occupation on firing characteristics have been particularly well studied for

CA1 pyramidal cells. A conspicuous feature of CORT actions on cellular activity in the hippocampus is the apparent lack of effect when neurons are studied under basal conditions. Only when neurons are shifted from their basal condition (e.g., by the action of neurotransmitters) do CORT effects become visible. The general picture emerging is that conditions of predominant MR activation (i.e., at the circadian trough at rest) are associated with the maintenance of neuronal excitability, so excitatory inputs to the hippocampal CA1 area result in considerable excitatory hippocampal output. In contrast, additional GR activation (e.g., following acute stress) generally depresses the transiently activated CA1 hippocampal output. A similar effect is seen after adrenalectomy (ADX), indicating a U-shaped dose–response dependency of these cellular responses to corticosteroids. Most of the CORT effects on hippocampal physiology have been shown to depend on *de novo* protein synthesis and even on DNA binding of the GR, indicating that the effects on transcription of as yet unidentified target genes are responsible for the observed phenomena.

The U shape of CORT on neuronal excitability, which is determined by differential MR and GR activations, is reflected in a number of parameters. An intrinsic cellular property is the voltage-gated Ca current; this current is small under conditions of predominant MR occupation and is elevated when GRs become activated in addition. Basal and stimulus-induced intracellular Ca levels were also found to be increased by substantial GR activation, which may be explained by steroid effects on Ca-buffering or extrusion mechanisms. In accordance with these steroid effects, the Ca-dependent accommodation and after-hyperpolarization (AHP) amplitude were found to be small with predominant MR activation.

MR and GR activations also modulate the responses to several neurotransmitters. With respect to amino acid-mediated synaptic transmission in the hippocampus, responses to both excitatory (glutamatergic) and inhibitory (GABAergic) inputs are maintained at a stable level when MRs are predominantly activated (i.e., with low CORT levels). When GRs become occupied, in addition, as a consequence of rising CORT levels, excitatory transmission (and thus CA1 hippocampal output) is reduced. At very high steroid levels, inhibitory networks are also impaired. These GR-mediated effects may involve the impairment of energy metabolism. The high efficiency of amino acid transmission with predominant MR activation is also reflected in long-term plastic changes involving this hippocampal network. Plasticity-related phenomena are most pronounced with moderate CORT levels so that most of the MRs and only part of the GRs are activated; when CORT levels are either

reduced or enhanced, synaptic potentiation/depression is far less effective. Thus, the varying concentrations of CORT as a consequence of stress will have consequences for the efficacy of synaptic potentiation in the hippocampus.

In addition to amino acid input, hippocampal neurons also receive considerable input mediated by biogenic amines such as acetylcholine, norepinephrine, and serotonin. Norepinephrine acts via a β -adrenergic receptor to increase excitability of the CA1 hippocampal area. High CORT levels, occupying GRs, reduce the norepinephrine effect, again leading to a reduction in responsiveness of the hippocampal neurons.

Serotonin (5-hydroxytryptamine, 5-HT) evokes many different effects in the CA1 hippocampal neurons, of which 5-HT-1A receptor-mediated hyperpolarization of the membrane is most prominent. This hyperpolarization is small in amplitude with predominant MR occupation; additional GR activation increases 5-HT responses. This is seen both when CORT is applied exogenously and after acute stress. Although CORT through MR activation also downregulates 5-HT-1A receptor mRNA expression and binding capacity, acute functional impairment is probably not brought about through reduced binding capacity.

Effects on Neurotransmitter Systems

CORT influences many cell types in the brain, and it is worthwhile to analyze its effects at the level of neurotransmitter systems, as opposed to a single cell type or nucleus. Major targets for coordinate regulation through corticosteroid receptors are the serotonin, dopamine, and norepinephrine systems. Modulation may take place at the level of both the presynaptic cell and the postsynaptic cell. As for most aspects of CORT action, the effects are permissive in nature – the genomic effects of steroid receptor activation are revealed in the context of activated systems.

Serotonin: Coordinate Regulation via Mineralocorticoid and Glucocorticoid Receptors A concept of coordinate regulation via MRs and GRs has emerged for the serotonin system, particularly in relation to its projection on the hippocampus. Under basal conditions, when corticosteroid levels are low, there is predominant activation of MRs. As described earlier, the response of hippocampal 5-HT-1A receptors under these conditions is low. In addition, MRs in certain hippocampal areas suppress the expression of the 5-HT-1A receptor. Thus, a situation of predominant MR occupation is associated with low responses to serotonin in the hippocampus. Serotonin release in the hippocampus is increased during and after stress

conditions that are associated with increased levels of CORT, that is, increased activation of GRs in serotonergic and hippocampal neurons. When the stress-induced GR occupation is prevented, no increased release of serotonin is observed in animals. CORT acts via GRs, presumably on the activity of the rate-limiting enzyme for serotonin synthesis (tryptophan hydroxylase), and via the attenuation of negative feedback inhibition by serotonin in the serotonergic neurons in the midbrain. At the postsynaptic level in the hippocampus, acute GR activation leads to increased responses to 5-HT-1A receptor activation. Thus, whereas MR-mediated actions of CORT inhibit hippocampal responses, GR occupation is required for the stress-induced increased activity of serotonin cells and for the increased responsiveness of 5-HT-1A receptor-mediated responses.

When CORT is chronically elevated to levels in the GR-occupying range, hyporesponses to serotonin are observed in hippocampal neurons and endocrine challenge tests. It is unclear which molecular changes underlie the transition from stimulatory to inhibitory effects of high levels of CORT on serotonergic transmission.

Catecholamines Dopaminergic and catecholaminergic cells also depend on GR occupation for development and function. As in the case of stress-induced serotonin activity, increased activity of the mesolimbic dopamine system in the adult rat depends on GR activation. Dopamine (DA) release in the nucleus accumbens and neuronal and behavioral responses to dopamine agonists such as apomorphine are stimulated by CORT via GR. Sensitization to repeated treatment with drugs that increase dopaminergic transmission, such as cocaine, depend on GR activation. GR-mediated activation and sensitization of DA systems are important for understanding the relationship between stress and drug addiction in the context of individual response characteristics and have implications for psychopathology. Increased DA is involved in the symptoms of psychosis and depression, which are often associated with elevated basal levels of circulating CORT and escape from dexamethasone suppression.

In the periphery, there are clear effects of CORT on epinephrine – the expression of the PNMT gene in the adrenal medulla depends on GR activation. CORT also potentiates epinephrine responses at the target level. In the central nervous system, GRs are abundantly present in the majority of the neurons in midbrain norepinephrine cell groups. Although studies with ADX rats show a permissive function of corticosteroids for norepinephrine cells during ontogeny and stress (e.g., in relation to memory formation),

the effect of GR activation in these cells and their postsynaptic targets are not as clear as for other transmitters.

Postsynaptically, CORT region-dependently regulates adrenergic receptor expression; that is, it induces the inhibitory $\alpha 2$ receptor in the hypothalamic PVN. In the hippocampus, the electrophysiological effects of norepinephrine are attenuated via a GR-dependent mechanism. Stress levels of CORT reduce the cyclic AMP generation induced by norepinephrine acting via β -adrenergic receptors in the hippocampus.

Neuropeptide Systems In addition to the classical neurotransmitter systems, many peptidergic systems are controlled via corticosteroid receptors, both at the level of peptide synthesis and at the level of postsynaptic receptors. These peptides are involved in many aspects of brain function, including hypothalamic control of the HPA axis and regulation of metabolism and feeding. The best-studied examples are POMC-derived peptides, CRH and arginine vasopressin (AVP) because of their critical role in the activation of the HPA axis. Both CRH and AVP mRNA levels are suppressed by CORT in the parvocellular division of the PVN, presumably via GR activation. However, this type of regulation is cell type-dependent because in the amygdala CRH mRNA is upregulated by corticosteroids. In the hippocampus, corticosteroid receptors mediate the regulation by CORT of neuropeptide Y and dynorphin mRNA levels; in the caudate-putamen and nucleus accumbens, corticosteroid receptors mediate regulation by CORT of preproenkephalin, neurokinin A, and preprodynorphin mRNA levels.

Cellular Viability

Structural changes of hippocampal neurons were observed both with chronic absence and chronic overexposure to CORT, indicating that the steroid-dependent expression of genes is of crucial importance for hippocampal integrity.

Chronic Absence of Corticosteroids The removal of the adrenal glands results within 3 days in apoptotic-like degeneration of mature granule cells in the rat dentatus gyrus but not in other hippocampal fields. The degeneration and associated loss of synaptic function can be prevented by treatment with MR ligands. In contrast to most brain regions, the dentate gyrus shows neurogenesis even during adulthood, which can be blocked by chronic stress and adrenal steroids. Lack of MR activation as a consequence of ADX results in increased cell birth and cell death. It has been argued that MR activation maintains

the balance between cell birth and cell death in the dentate gyrus by enhancing the excitatory input to this region. However, newborn neurons in the dentate gyrus do not express corticosteroid receptors, suggesting that the steroid effects on neurogenesis are indirect and possibly involve the modulation of excitatory transmission and neurotrophins.

Chronic Exposure to High Corticosteroid Levels

Ample evidence now shows that chronic elevation of CORT levels leads to atrophy in parts of the hippocampus, as well as to increased vulnerability to excitotoxic insults. CA3 pyramidal neurons seem to be particularly vulnerable, although effects in the CA1 and dentate subfield have also been reported. Three weeks of restraint stress in rats causes the regression of apical dendrites of hippocampal CA3 pyramidal neurons. This effect is mimicked by 3 weeks of treatment with a high dose of CORT and does not occur when CORT secretion is blocked by cyanoketone treatment. The regression occurring after 3 weeks of high levels of CORT is reversible, and available data support the view that an imbalance of excitatory over inhibitory signals, leading indirectly to an enhanced Ca influx in the CA3 pyramidal neurons, contributes to the observed degeneration. Lack of neurotrophic capacity may also contribute to enhanced neuronal vulnerability. Indeed, chronic stress or the administration of CORT affects brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), and basic fibroblast growth factor (bFGF), and tumor growth factor (TGF) expression in the hippocampus.

A critical duration of overexposure to steroids is essential for the atrophy of CA3 neurons to develop; temporary high levels of the hormone decrease responsiveness to excitatory amino acids and reduce excitability. It is only in conditions of chronically enhanced corticosteroid exposure that local depolarization is sustained and the breakdown of inhibitory networks occurs. Hippocampal neurons are subsequently subjected to a substantial GR-dependent rise in intracellular Ca levels. Following this line of reasoning, the beneficial effects exerted by phasic activation of GRs are turned into damaging actions when GRs are activated chronically.

Behavior and the Stress Response

The differential effects on neuronal functioning that CORT exerts via MRs and GRs, and the differential occupation of these receptors as a function of the behavioral state of the animal, suggest fundamentally different roles for CORT via MR- and GR-mediated processes. MRs are occupied by basal levels of CORT and thus mediate tonic hormonal influences. This

might function to prepare the animal for upcoming challenges and determine the magnitude and/or nature of initial responses. This proactive mode of control includes the effects on the processing of sensory information, interpretation of environmental stimuli, and selection of the appropriate behavioral strategy. GRs, however, are occupied after plasma CORT levels have become elevated after challenges/stress. Their role may be to generally mediate reactive processes that serve to restore homeostasis, to facilitate behavioral adaptation of the animal, and to prepare the animal for a next exposure to a stressor.

Corticosteroid Receptors and Hypothalamic-Pituitary-Adrenal Axis Control

Both MRs and GRs are involved in the feedback control of HPA axis activity, but the temporal and neuroanatomical aspects of feedback differ substantially for each receptor type. Apart from primary feedback sites, the hippocampus has received a lot of attention, particularly because it contains the highest concentrations of both MRs and GRs in the brain.

Pituitary corticotrophs and PVN (being part of the HPA axis) contain the primary feedback sites for stress levels of CORT. The effects of CORT on pituitary, PVN, and brain-stem catecholaminergic nuclei involve the activation of GRs. Limbic inputs impinging on the PVN (via hypothalamic GABAergic neurons) express high levels of the MR in addition to the GR, suggesting the dual regulation of these inputs by CORT. Moreover, the effect of these inputs can be either inhibitory on HPA activity (from hippocampus) or excitatory (e.g., from amygdala).

Pharmacological experiments in rats have shown that MR occupation suppresses HPA axis activity under basal conditions around the circadian trough; in ADX animals, hormone levels can be normalized with a median inhibitory concentration (IC_{50}) of approximately 0.5 nM in terms of circulating free CORT, which is in the range of the MR K_d value. In intact animals, MR antagonists lead to an increase in CORT levels at the time of the circadian trough. Accordingly, MR activation serves to control HPA axis activity in a proactive manner.

At the circadian peak, much higher levels of exogenous corticosteroids are required to normalize ADX-induced increases in HPA axis activity, and half-maximal suppression is achieved by a free concentration of approximately 5 nM, close to the K_d of GRs. However, the exclusive activation of GRs is insufficient to suppress the circadian peak, and MR activation appears to be indispensable. One episodic rise in CORT levels by injection or ingestion via the normal evening drink is sufficient to occupy both receptor types and to maintain ACTH levels with

small amplitude changes over the 24-h period. These GR-mediated effects observed after exogenous glucocorticoids thus are also involved in maintenance of HPA activity.

Elevated CORT facilitates the termination of the HPA response to stress, and various temporal (fast and slow feedback) domains have been distinguished. These GR-mediated effects triggered in response to stress represent the reactive mode of feedback operation.

Hippocampal Mineralocorticoid and Glucocorticoid Receptors Lesioning and electrical stimulation studies suggest an overall inhibitory influence of the hippocampus on HPA activity. The effects of intracerebroventricular MR antagonists in rats (see earlier discussion on the elevation of basal trough levels of CORT and enhanced adrenocortical responses to novelty) are likely mediated by hippocampal MRs. Consistent with the MR specificity of the response, a CORT implant in the dorsal hippocampus has been shown to suppress ADX-induced elevations in ACTH levels, whereas dexamethasone implants were ineffective. Finally, the systemic administration of spironolactone can increase basal HPA activity in humans, although this response has not been noted in all studies. Thus, hippocampal MRs appear to mediate the effect of CORT in maintaining the tone of basal HPA activity.

GR activation in the hippocampus, however, may not be involved in negative feedback but, rather, serves to suppress hippocampal output, leading to a disinhibition of the HPA axis. In fact, there is some experimental evidence that the intrahippocampal (in contrast to intracerebroventricular) administration of GR agonists does lead to an activation of the HPA axis. The nature of HPA regulation via hippocampal MRs and GRs is also consistent with the cellular actions they evoke in the hippocampus; predominant MR activation (comparable with local antiglucocorticoid application) maintains hippocampal excitability and, through transsynaptic inhibitory projections to the PVN, basal HPA activity. Conversely, with rising CORT concentration, GR activation suppresses the hippocampal output, resulting in a disinhibition of PVN neurons. The functions mediated by both receptor types are linked. A deficiency in an MR is predicted to allow a CORT response more readily, thus leading to more pronounced GR-mediated effects. This illustrates the importance of balance in MR- and GR-mediated effects involved in HPA regulation.

Indirect Effects Observations on HPA regulation have often been made without consideration of the

steroid effects on higher brain functions involved in arousal and processing of information. Brain areas projecting to the PVN have profound and long-lasting consequences for feedback regulation. Many systems with inputs to the PVN generally express GRs and contain numerous colocalized neuropeptides, which also regulate PVN activity in their own right.

The activation of a particular afferent neuronal network innervating the PVN area is stressor-specific and depends on the nature of the stimulus. If it constitutes a direct threat to survival through physical stressors (e.g., respiratory distress, hemorrhage, inflammation, infection, and trauma), the ascending aminergic pathways promptly activate the autonomic and neuroendocrine centers in the hypothalamus. If sensory stimuli are subject to appraisal and interpretation, processing in higher brain regions is required, which may subsequently lead to the modulation of GABAergic tone and a change in synthesis of CRH, AVP, and other neuropeptides of the PVN secretagogue cocktail. The activation of brain stem and limbic circuitry is not separated but is, in fact, mutually interactive because stress-induced CORT enters the brain readily and feeds back on all components of the neural stress circuitry, but in a context-dependent manner.

Control over Learning and Memory via Mineralocorticoid and Glucocorticoid Receptors

The activation of central corticosteroid receptors does not necessarily cause a behavioral change but, rather, influences information processing, thereby affecting the likelihood that a particular stimulus elicits an appropriate behavioral response. For example, the GR-mediated effects on the dopaminergic reward system may render animals more susceptible to addiction but by themselves cause no such state. Through coordinate MR- and GR-mediated actions in higher brain areas (e.g., the neocortical regions and limbic areas such as the hippocampus, septum, and amygdala), CORT affects learning and memory processes. Therefore, when studying the modulation of behavioral responses by CORT, the time and duration of the hormone action, as well as its context, need to be considered.

The hippocampal formation plays a key role in animals' reactivity to novelty and provides an essential contribution to learning and memory. Stress hormones, including CORT, are secreted during learning and are necessary for the establishment of an enduring memory. In this context, the role of CORT on the acquisition, consolidation, and retrieval of information has been studied for more than 4 decades. Many different tests revealed that the administration of exogenous CORT in the appropriate

temporal context (i.e., in close relation to training) potentiated memory in a dose-related fashion. From studies involving the use of specific corticosteroid receptor antagonists, antisense oligonucleotides, and transgenic animals, it is clear that these effects of corticosteroids require GR activation. These effects via GR in the context of stress-induced elevated hormone levels represent a reactive mode of action.

Studies with specific antagonists have shown that MRs modulate ongoing behavioral activity, as demonstrated by the effects of MR blockade during, but not after, the training session. These effects mediated by the MR regulate sensory integration underlying the evaluation of environmental information and response selection and thus have the capacity to subsequently affect memory storage for spatial and avoidance behavior. MR-mediated effects on behavioral response selection and reactivity may again be interpreted as a proactive mode of action, aimed to maintain homeostasis.

Thus, hippocampal MRs mediate the effects of CORT on the appraisal of information and response selection, whereas GR function does not so much modify these aspects of sensory integration as promote the processes underlying the consolidation of acquired information. However, exposure to high CORT levels in a different context (e.g., as a consequence of an additional stressor) may interfere with the consolidation processes because it may signal different, and more relevant, stimuli to the animal. The MR- and GR-mediated effects on information processing facilitate behavioral adaptation. This also promotes the inhibitory control exerted by higher brain circuits over HPA activity.

Corticosteroid Receptors in Pathology

The inappropriate activation of corticosteroid receptors through aberrant levels of hormone leads to well-known pathologies: Cushing's disease, immunosuppressed states (glucocorticoid excess), Addison's disease (glucocorticoid deficiency), and pseudomineralocorticoid excess states that are associated with high blood pressure. In the brain, the situation is much more complex. Depending on the region, both MRs and GRs can mediate the effects of CORT, and the balance in activation of these two receptor types may be critical in determining the effects of CORT on neuronal systems. For example, animal studies show that the balance of MR- and GR-mediated activities in hippocampal circuits determines excitability, stress responsiveness, and behavioral reactivity. Also, the effects of corticosteroid receptor activation often depend on the cellular context as a result of cross-talk with other signaling cascades. Genetically determined

differences in any of the signaling pathways involved can lead to a predisposition to adverse effects of CORT.

Significant changes in CORT signaling in the brain can result from chronic stress exposure and the inefficient operation of the HPA axis, resulting in over- or underexposure to circulating CORT, and from genetically determined or acquired changes in relative abundance of MRs and GRs (and associated factors). All these changes may lead to disturbances in mood and affect and in neurodegenerative phenomena via direct actions on relevant brain structures, as well as via the modulation of the HPA axis activity. However, the specific contribution of brain MRs and GRs to these cognitive and affective deficits has not been established.

Disturbed CORT signaling in brain appears to be causally involved in enhancing vulnerability to depression. In this context, it is extremely interesting that the tricyclic antidepressants not only restore 5-HT and noradrenergic transmission in brain but also increase the expression of brain corticosteroid receptors, in parallel with the normalization of HPA tone. Recent data suggest that the blockade of central GRs can be used as an effective treatment against psychotic major depression. In contrast to depression, posttraumatic stress disorder, chronic fatigue syndrome, and fibromyalgia are associated with a hypoactivity of the HPA axis.

Evidence from animal experiments and in humans shows that a dysregulated HPA axis, corticosteroid receptor deficits, and elevated CORT levels during stress are associated with age and may lead to an enhanced vulnerability to neurodegenerative disorders, particularly in the hippocampus. GR-mediated impairment in the energy metabolism of hippocampal pyramidal cells is thought to play a role here. The glucocorticoid cascade hypothesis has received much attention over the last years – hypercorticism leads, over time, to damage to the hippocampus, which in turn leads to the disinhibition of the HPA axis and further elevation of CORT levels. A central assumption of this hypothesis is that hippocampal GRs are thought to promote escape from negative feedback via downregulation. However, there is little evidence for a direct negative feedback function of hippocampal GRs; the role of the hippocampus appears to be indirect and involved more with the shutoff of the neural activity that drives HPA output, operating in concert with the output from the amygdala and pathways via the bed nucleus of the stria terminalis. Thus, the mechanisms that lead to the progressive hyperactivity and dysregulation of the HPA axis in some individuals as they age are evidently more

complex than envisioned in the glucocorticoid cascade hypothesis, and their elucidation will require a more extensive understanding of the role of other brain structures than the hippocampus and the hypothalamus in HPA regulation.

Binding of Corticosteroid-Binding Globulin to Cell Membranes

Measurement of Corticosteroid-Binding Globulin

Use of Corticosteroid-Binding Globulin to Measure Steroids by Competitive Protein Binding

Glossary

Affinity

The degree of association between two entities; expressed as the ratio of complexed to free reactants at equilibrium (the affinity constant), which is the reciprocal of the dissociation constant.

Discovery and Definition of Corticosteroid-Binding Globulin

Biological Role of Corticosteroid-Binding Globulin

Physical Characteristics of Corticosteroid-Binding Globulin

Physiological Variation

<i>Binding capacity</i>	An expression of the number of binding sites available for a ligand.
<i>Corticosteroids</i>	Steroids made by the adrenal cortex.
<i>Ligand</i>	An entity bound by noncovalent forces to another (usually larger, usually protein) entity.
<i>Steroids</i>	Molecules containing the perhydrocyclopentanophenanthrene nucleus, including sterols, bile acids, sex hormones, adrenocortical hormones, cardiac glycosides, and sapogenins.

Discovery and Definition of Corticosteroid-Binding Globulin

The presence of a human plasma protein binding corticosteroids with high affinity ($5-8 \times 10^7 \text{ M}^{-1}$) and low capacity (10^{-9} – 10^{-8} M) was discovered in 1956 independently by I. E. Bush and by W. H. Daughaday. In 1958, A. A. Sandberg and W. R. Slaunwhite discovered a similar protein, which they called transcortin and which turned out to be identical with corticosteroid-binding globulin (CBG). Similar proteins have been found, many by U.S. Seal and R. P. Doe, in almost all species of vertebrates. A CBG-like protein has even been described in the eukaryotic fungus *Candida albicans*, with a K_a of $1.6 \times 10^8 \text{ M}^{-1}$ at 0°C , which might represent a primitive form of either the mammalian glucocorticoid receptor or of CBG.

CBGs differ from species to species in their relative affinities for various steroids. Most bind cortisol and corticosterone the most strongly; many bind progesterone very strongly; they bind aldosterone weakly. The guinea pig possesses a second corticosteroid-binding protein – progesterone-binding globulin (PBG) – in addition to CBG; PBG rises more than 100-fold during pregnancy. Although CBG binds testosterone and estradiol weakly, many species have, in addition to CBG, a sex hormone-binding globulin (SHBG), which binds these and related steroids more strongly. CBG is very low or undetectable in the plasma of the spiny anteater (an egg-laying mammal) and of the New World squirrel monkey.

Biological Role of Corticosteroid-Binding Globulin

Serum proteins such as albumin and CBG increase the solubility in biological fluids of steroids that are otherwise poorly soluble in aqueous solutions. However, the limited capacity and high affinity of CBG for glucocorticoids and progesterone has led to the accepted model of CBG action in which CBG provides a plasma store of tightly bound steroid that is less able to diffuse into cells, whereas free or unbound steroid

passes freely across cell membranes to initiate hormone action. Because the binding to CBG is rapidly reversible, steroid may quickly be transferred from the bound to the free state. Thus CBG is a major determinant regulating the concentration of the hormones that it binds. On exposure to serine protease from inflammatory granulocytes, CBG is cleaved and releases all or most of its bound steroid; thus, it seems likely that this process may permit the enhanced delivery of cortisol to sites of inflammation. The binding of CBG to cell membranes and entry into cells may also be important in its action.

Changes of CBG in fetal life occur as a result of normal development, possibly promoting the delivery of glucocorticoids to sites of rapid growth and tissue remodeling.

In the human, the unbound fraction of cortisol is usually approximately 10% of total cortisol; in Cushing's syndrome, in which CBG levels are decreased and total cortisol levels increase, this fraction rises to approximately 25% of the total, whereas in adrenal insufficiency it falls to approximately 6% of total cortisol.

Physical Characteristics of Corticosteroid-Binding Globulin

Structure

The molecular weight of CBG is 50–60 kDa, and there is one cortisol-binding site per molecule. The degree of sequence similarity among species is 60–70%. CBG is a monomeric glycoprotein (with the possible exception of New World primate CBGs, which may circulate as dimers) consisting of approximately 380 amino acids with a molecular weight of approximately 42 000 (Figure 1). Relatively large differences in the apparent molecular size among species is probably due to variations in carbohydrate composition. The human CBG sequence is thought to contain six consensus sites for N-glycosylation. Only two of these sites have been retained throughout evolution, and these are located in highly conserved regions and may therefore be functionally important. The gene for CBG is localized to chromosome 14. The deduced primary structure of CBG suggests a greater than 30% homology with the SERPIN (serine protease inhibitor) superfamily of proteins. This family includes α_1 -proteinase inhibitor (A1-P1), α_1 -antichymotrypsin (ACT), and thyroxine-binding globulin. A1-P1 and ACT are located close to the region containing the human CBG gene. The PBG of guinea pig has a molecular weight of approximately 80 000 kDa and has one binding site per molecule. Its properties have been reviewed by Westphal.

Figure 1 Primary structure of the human CBG precursor. The N-terminus of the mature polypeptide is inferred from published data, and the proposed signal peptide comprises 22 amino acids, shown in shaded circles. Potential sites for N-glycosylation are shown as squares, with a filled square indicating the site that is known to be used, and $\pm$ representing partial utilization. The elastase cleavage site is marked by an arrow, and the cysteine residue, which is conserved between species, is indicated. From Hammond, G. L. (1990), *Molecular properties of corticosteroid binding globulin and the sex-steroid binding proteins*, *Endocrine Reviews* 11, 65–79. Copyright 1990, The Endocrine Society.

Biosynthesis

The liver is the main site of CBG synthesis, and CBG is synthesized by hepatocytes in culture. CBG mRNA has been detected in the extrahepatic tissues (the spleen, ovary, testis, and lung) of various species but only in low amounts, and their significance is uncertain. CBG production is regulated independently in mother and fetus. Guinea pig PBG is made in only very small amounts by the liver, and the large rise in pregnancy is due mainly to synthesis by the placenta.

Degradation of Corticosteroid-Binding Globulin

The half-life of human CBG is approximately 5 days under usual circumstances but is decreased with severe stress. The serum clearance in early postnatal life in the rat is approximately twice as rapid (50% in ~ 7 h) as in the adult animal (~ 14 h).

Temperature Dependence

CBG binding in all species is temperature dependent, being maximal at approximately 4°C . At temperatures above 60°C , it is rapidly destroyed (in ~ 20 min).

Stability is increased at higher cortisol concentrations. Between 37 and 40°C there is a rapidly increasing rate of dissociation, which may be important physiologically in febrile states, resulting in a more rapid release of cortisol to the tissues. Similarly, local elevation of temperature as a consequence of inflammation may contribute to more available cortisol at these sites. Binding activity is usually retained after a single freezing but is lost with repeated thawing and freezing. Many CBGs in serum are stable for long periods at 4°C ; human CBG is stable for months or years provided bacterial contamination is prevented (e.g., by the addition of 0.1% sodium azide). Guinea pig PBG is more resistant to heating than most CBGs.

Affinity

The affinity constant for the binding of cortisol to human CBG is approximately $1 \times 10^9 \text{ M}^{-1}$ at 4°C and $5 \times 10^7 \text{ M}^{-1}$ at 37°C . The CBGs of most other species are in the range of 10^7 – 10^9 M^{-1} at 4°C and are also lower at 37°C . A relatively high association constant ($0.9 \times 10^8 \text{ M}^{-1}$) has been observed for ovine plasma at 37°C .

pH

Binding activity is also dependent on pH; for human CBG, it is maximal at approximately pH 8, but irreversible denaturation takes place below pH 5. In the guinea pig, PBG is more resistant to low pH than is CBG.

Electrophoresis

Electrophoretically, CBG behaves as an α_1 -globulin.

Relationship to Albumin Binding

Steroids are also bound by albumin in all species. The free fraction is usually 6–14% of the total, with the CBG-bound fraction being 67–87% and the albumin-bound fraction 7–19%. In the squirrel monkey, approximately one-half is free and one-half is bound to albumin; this is the only vertebrate species in which CBG appears to be virtually absent.

Effect of Reducing Agents

The binding of cortisol and progesterone to purified human CBG is reversibly decreased by adding strong reducing agents such as dithiothreitol and β -mercaptoethanol but not by the milder sodium ascorbate. Only the affinity is decreased; the number of binding sites remains the same.

Binding Specificity

Mammals Although the specificity and affinity of the steroid-binding site vary among species, maximal binding usually coincides with the biologically more important glucocorticoid (either cortisol or corticosterone) in a given species. The ratio of cortisol to

corticosterone varies widely among species, and the relative binding affinities for the two steroids also differ widely. In the green iguana there is high binding of cortisol (3056 nmol l⁻¹) but no detectable binding of corticosterone, whereas in the porcupine fish the binding to corticosterone (1250 nmol l⁻¹) is much higher than that of cortisol (67 nmol l⁻¹). For human plasma, Dunn et al. have calculated the binding distribution of endogenous steroids in normal men and in nonpregnant and pregnant women (Table 1).

In many species, progesterone, 11-desoxycortisol and desoxycortisol are also bound to CBG (Table 2). Alterations in ring A of strongly binding steroids cause a drastic drop in binding affinity; this is less marked in the CBG of avian species and in PBG.

Progesterone-binding globulin of guinea pig Whereas in human and many other species, CBG binds progesterone strongly, the guinea pig is the only species known to possess PBG, a separate CBG-like protein, which binds progesterone almost exclusively.

Marsupials The affinity of CBG in marsupials is similar to those of mammals, but the binding site concentrations are generally lower.

Synthetic steroids Some synthetic steroids, such as prednisolone, which is a glucocorticoid, and danazol (WII 131), which is not, also bind to CBG and compete with cortisol for binding sites. Dexamethasone, another synthetic glucocorticoid, is not bound to human CBG, but it does bind to chicken and dog CBG. Bovine serum is unusual in that, in addition to

^cPBG; serum from guinea pig in late pregnancy was used.

a CBG, which binds cortisol strongly, it contains a protein that binds triamcinolone acetonide, a synthetic glucocorticoid, approximately 50 times more strongly than cortisol.

Physiological Variation

In the human, the CBG binding capacity of men and women is similar (600–700 nM) and changes little from ages 1–60 years. Plasma levels of CBG vary from 10 to 500 nM in most vertebrate species. They are exceptionally high in the green iguana (3000 nM) and squirrel (2500 nM), and they are low in New World monkeys – only 1–10% of those in Old World primates and humans. The affinity is also lower, resulting in a much higher fraction of unbound plasma cortisol, possibly to compensate for the target organ resistance to glucocorticoids, which characterizes this group. In the squirrel monkey, the only mammal known that appears to lack CBG, half the cortisol is albumin-bound and half is free. In rat and guinea pig, female CBG levels are approximately twice those of males, a difference that is abolished by neonatal gonadectomy.

The concentration of CBG in the lymph is slightly lower than that in the blood, whereas concentrations in the synovial fluid and pleural effusion are higher and those in the spinal fluid and amniotic fluid are very low. CBG passes into milk – in human milk the concentration has been reported to be 1–15% that of plasma and in rat milk approximately 25% that of plasma. A CBG-like protein that binds progesterone strongly has been reported in human breast cyst

fluids. Because there is little or no CBG or albumin in saliva, salivary cortisol is often used as an index of free cortisol; however, the salivary gland contains 11-hydroxysteroid dehydrogenase type 2, which converts approximately half the cortisol to cortisone, so salivary values are approximately one-half those of free cortisol in plasma.

Pregnancy

In human pregnancy, CBG levels rise to levels more than twice those of nonpregnant women. The affinity is unchanged. The increase is due to the increased levels of estrogens in pregnancy. Progesterone binding, both free and total, increases steadily until the end of pregnancy; the free fraction rises from 6% of total at week 24 to 13% at week 40.

Elevated levels of CBG, up to 30-fold, have been observed by Seal and Doe to occur during pregnancy in mammals with a hemochorial type of placentation (rodents, cats, dogs, moles, shrews, manatees, and most primates) but not in those with other types such as endotheliochorial, choriovitelline, epitheliochorial, or syndesmochorial; the biological significance of this difference is not known. The increase in CBG is minimal in the rat (see Figure 2). In the guinea pig, CBG rises three- to fourfold, whereas PBG rises more than 100-fold. PBG differs from CBG in that it is not stimulated by estrogen.

Fetus and Neonate

Whereas fetal corticosteroid levels rise in many species during pregnancy, CBG levels vary considerably with species; in many, the levels fall rapidly

Figure 2 Serum CBG concentrations in fetal and neonatal rats (●) and in pregnant and lactating rats (○). The concentrations are expressed as means $\pm$ SD, and the number of animals or pools (days 16–18 for the fetuses) is given in parentheses. The normal serum concentration of four female and four male rats on day 154 of life is indicated on the right. From Van Baelen, H., Vandoren, G. and DeMoor, P. (1977), Concentration of transcortin in the pregnant rat and its foetuses, *Journal of Endocrinology* **75**, 427–431. Reproduced by permission of the Society for Endocrinology.

postpartum. In most species, early postpartum fetal CBG levels are lower than adult values.

Compared to the adult (700 nmol l^{-1}), CBG levels are lower in the human fetus and neonate, approximately 250 nmol l^{-1} in late gestation and immediately postpartum; rise to approximately 500 nmol l^{-1} by 30 days postpartum; and rise to adult levels by several months of age.

The level of CBG in the fetal rat rises from approximately 1.3 mol l^{-1} at 16 days gestation to a maximum of approximately $2 \mu\text{mol l}^{-1}$ at 28 days, after which it falls rapidly and subsequently rises slowly to adult values by 6 weeks (Figure 2). Thus CBG production is apparently independently regulated in mother and fetus. The decline in fetal rat CBG before birth may promote an increase in free corticosterone levels necessary for lung maturation. Despite the low neonatal values of CBG in rats, hippocampal glucocorticoid receptor occupancy/translocation (i.e., hormone-bound receptor) was noted by Viau et al. to be similar at all ages, both under basal conditions and following stress.

The sheep differs from this pattern; fetal CBG levels increase markedly over the last 2 weeks before term, from 50 nmol l^{-1} cortisol bound to 250 nmol l^{-1}

at term, whereas unbound and albumin-bound cortisol increase from 3 to 58 nmol l^{-1} and the total cortisol rises 13- to 15-fold. During this time, no changes occur in the maternal plasma. After birth, the CBG binding capacity of the neonate falls rapidly to about 90 nmol l^{-1} by 4 days and to 17 nmol l^{-1} by 14 days; total and free corticoids also decrease, but more slowly. The increase of CBG in fetal sheep plasma before term has been shown to depend on an intact fetal pituitary. The affinity of fetal CBG is similar to that of adult CBG. Possibly the rise in CBG contributes to the onset of parturition because the administration of glucocorticoids induces parturition in this species.

In the baboon, fetal serum CBG capacity at 100–132 days gestation is similar to that of the mother and decreases at term by half. Fetal serum cortisol is low ($\sim 100 \text{ nmol l}^{-1}$) before 168 days gestation and reaches approximately 1400 nmol l^{-1} after term delivery. Affinity constants are the same throughout.

Hereditary Deficiency

Hereditary deficiency has been shown in a few human families, in which the concentration was reduced to approximately one-half the normal. However,

familial low levels of CBG are rare and no convincing case of completely absent CBG in the human has been documented, suggesting that absence of CBG may be a lethal mutation, although cases with low CBG have no clinical apparent abnormalities. CBG appears to be identical in all human races. A variant of CBG, containing a slightly altered carbohydrate, occurs in pregnant women and accounts for 4–14% of total plasma CBG at term; its function is not yet clear.

Changes with Diet

Slight changes occur with diet; a high carbohydrate diet may result in a 20% fall in CBG.

Possible Fatal Drop in Corticosteroid-Binding Globulin

A remarkable change in CBG occurs in the male *Antechinus stuartii*, a shrewlike marsupial. In this species, all the males die within 3 weeks of the beginning of their first and only mating period in late winter. Over this period there is a precipitous fall in CBG levels, whereas the plasma corticosteroid concentrations remain high. No such changes occur in the females. Because these changes in the males result in a large increase in free cortisol, it is possible that the males die of hypercorticism.

Response of Corticosteroid-Binding Globulin to Stress

In humans, patients with septic shock or multitrauma have markedly low CBG levels in the early phase, with levels gradually increasing to normal by 7 days; in contrast, the free cortisol index shows high levels in the early phase, decreasing toward normal during the second phase. These observations suggest that CBG plays an active role by regulating availability to target tissues.

Acute severe stress in rats (e.g., immobilization for 1 h or tail shocks over 2 h) causes a fall in CBG, which is apparent by 6 h, maximal at 24 h, and persists for 24–48 h. Despite the low values of CBG in the neonatal rat, in response to stress (restraint for 1 h or separation from the mother) the adrenocorticotrophic hormone (ACTH) and the free corticosterone levels increase, and this increase persists for 48 h. Such increases are associated with an increased glucocorticoid receptor occupancy/translocation similar to that of stressed adults.

In rats in which an inflammatory process was induced by a subcutaneous injection of turpentine, CBG levels had decreased by two-thirds, whereas the corticosteroid levels were very high. Although the high corticosteroid levels might be expected to decrease CBG levels, the effect was still present after

adrenalectomy, suggesting that changes in glucocorticoid concentration are not necessary for this change. At the same time as the CBG levels were low, the levels of haptoglobin, an acute-phase serum protein rose 6- to 10-fold. CBG levels in pregnant rats treated similarly showed a threefold decrease of CBG, whereas their 19-day-old embryos were not affected.

Alexander and Irvine found that social stress in horses caused a decrease in CBG binding capacity (horses new to a herd were confined in a small yard with dominant resident horses for 3–4 h daily for 3–14 days). This decrease in CBG, seen after 3–4 days and increasing over the 2-week period, was accompanied by an increase in free cortisol, so that the total cortisol concentrations remained unaltered.

In comparing the homology of CBG cDNA, it was found that there is no sequence homology with any steroid hormone receptor. However, the homology with the SERPIN superfamily of proteins exceeds 30%. The proteins in the SERPIN superfamily share a typical tertiary structure responsible for the marked inhibition of serine proteases. In contact with neutrophil elastase, released by neutrophils in large amounts at sites of inflammation, CBG is cleaved, resulting in a 10-fold fall in its affinity for cortisol and thereby releasing its cortisol. Such a mechanism may permit the free cortisol to remain in high concentration at sites of inflammation while maintaining basal free cortisol concentrations at other sites.

Response of Corticosteroid-Binding Globulin to Other Pathological Factors in Humans

Increases in CBG also occur with the administration of oral contraceptive agents or other estrogen-containing preparations that increase synthesis. Tamoxifen and clomiphene also raise CBG levels. On the other hand, androgens such as testosterone decrease them; other anabolic steroids such as methandrostenedione and oxymetholone increase them slightly. CBG levels are reduced in patients with liver cirrhosis, nephrotic syndrome, and, in some cases, hypertension and hyperthyroidism, whereas elevated levels have been reported in some cases of acute leukemia, lymphoma, chronic active hepatitis, lung cancer, untreated adrenal insufficiency, adrenocortical hyperplasia, and disorders of male and female puberty. A slightly enhanced CBG capacity has been observed in juvenile-onset diabetics. A decreased CBG concentration, corrected by vitamin B₁₂ administration, has been observed in some cases of pernicious anemia.

Glucocorticoids decrease CBG levels, so increased CBG levels are found after adrenalectomy, whereas decreased levels are found in Cushing's syndrome (whether endogenously or exogenously produced).

A rapid fall in CBG occurs in septic shock, reaching a nadir at approximately 24 h due to a marked increase in rate of removal because the half-life of CBG is approximately 5 days; this may occur by proteolysis at sites of inflammation. In cases of shock due to severe acute infection by *Candida albicans*, the CBG activity may be virtually absent.

Binding of Corticosteroid-Binding Globulin to Cell Membranes

A number of reports suggest that CBG binds to various cell membranes, including prostate, epididymis, testis, mammary carcinoma cells, uterus, pituitary, kidney, spleen, muscle, lung, and placenta. Although many of these await confirmation, it appears that CBG does bind to some cell membranes with a K_D of approximately 0.9 μM at physiological temperatures. This binding requires calcium and/or magnesium ions and is negligible at 4 or 23°C. The physiological significance of this binding is still unknown. In rat white adipose tissue, del Mar Grasa et al. found that CBG was seen in a thin layer surrounding the cells; they suggested that CBG in this location may act as a protective barrier limiting the access of glucocorticoids to adipocytes.

Measurement of Corticosteroid-Binding Globulin

CBG is measured either by its binding capacity for glucocorticoids (described by Westphal), by radioimmunoassay, or more recently by enzyme-linked immunosorbent assay.

Use of Corticosteroid-Binding Globulin to Measure Steroids by Competitive Protein Binding

Human CBG was the first protein used for the determination of glucocorticoids by B. E. P. Murphy in 1963 using the principle of competitive protein binding (displacement analysis and radiotransinassay), which is identical to that of radioimmunoassay. In this type of analysis, the specificity of the assay depends on the binding properties of the binding protein and the conditions under which the assay is carried out. The endogenous steroid or ligand is quantitated according to its competition with a tracer ligand, usually a radioisotopic form of the endogenous ligand, for binding sites on the protein, and the displacement of the tracer steroid is estimated against a series of standards of the ligand being measured. Thus, for example, the binding of radiolabeled cortisol will

be gradually lowered by increasing amounts of endogenous cortisol, giving a standard curve.

Although no CBG is entirely specific for cortisol alone, the amounts of competing steroids in human plasma are usually small. In human pregnancy, progesterone is an important competitor, but it can be easily removed by extraction into hexane, which does not extract cortisol; the extracted progesterone can then itself be measured using CBG and a series of progesterone standards. Even better, progesterone may be measured using PBG of pregnant guinea pig serum, which has high specificity for progesterone and very little for cortisol or corticosterone. Because no protein is ever specific for a single ligand (and monoclonal antibodies are no exception), care must be taken to ensure that specificity is achieved under the conditions used. Because of the high affinity of CBG for cortisol, the sensitivity of such a method is very great, so that picogram amounts are readily measured. If chromatographic techniques are employed, other competing steroids can also be measured. Because different species of CBGs provide proteins with varying specificity and affinity, they can be used for the assay of many different steroids ([Table 1](#)). Maximum sensitivity is achieved by using a high dilution of the protein and a low volume for equilibration (usually 0.1 ml). Precision and accuracy are similar to those of radioimmunoassay.

Glossary

11 β -Hydroxy-steroid dehydrogenase type 2 (11 β -HSD2) An enzyme in mineralocorticoid target cells (e.g., the kidney and some brain cells) that inactivates glucocorticoids, thus allowing aldosterone access to the mineralocorticoid receptors; may also

Adrenocorticotrophic hormone (ACTH) Cytokines

Glucocorticoid receptors (GRs)

Glucocorticoids (GCs)

Hypothalamic-pituitary-adrenal (HPA) axis

regulate glucocorticoid concentrations in some glucocorticoid target cells.

A peptide that controls the synthesis and secretion of glucocorticoids from the adrenal cortex.

Peptide hormones, produced particularly by activated cells of the immune system, that transmit signals between cells and organs via specific cell membrane receptors.

Protein molecules with a relatively low-affinity ($K_d \sim 40$ nM) specific binding site for glucocorticoids that are present in the cytoplasm and nucleus of almost all nucleated cells; bind to chromatin and regulate gene expression when activated by ligand binding.

Cortisol and corticosterone, the steroidal stress hormones produced by the adrenal cortex under the control of ACTH; they act on almost all nucleated cells, influencing innumerable metabolic and physiological functions. The term also refers to synthetic analogs such as dexamethasone.

The physiological link between the central nervous system and adrenocortical production of GCs. In response to signals including stress, decreased feedback from GCs, and certain cytokines, the hypothalamus produces the peptides

Mineralocorticoid receptors (MRs)

corticotropin releasing hormone and vasopressin, which regulate the pituitary output of ACTH.

Protein molecules with high-affinity ($K_d \sim 2$ nM) specific binding site for aldosterone, cortisol, and corticosterone; present in the cytoplasm and nucleus of the kidney, brain, and some other cells. It binds to chromatin and regulates gene expression when activated by ligand binding.

Mineralocorticoids

Aldosterone, the steroid hormone produced in the adrenal cortex under control of angiotensin II, which stimulates mainly kidney cells to reabsorb sodium and water; also used for the much weaker natural steroid deoxycorticosterone and for synthetic analogs.

Glucocorticoids, Mineralocorticoids, and Stress

Although Thomas Addison's discovery of the essential role of the adrenal gland for survival dates back to the mid-nineteenth century, it was not until the 1930s that Hans Selye promulgated the physiological concept of stress and implicated the hormones of the adrenal cortex in protecting the organism against stress. By then Walter Cannon had established the role of the adrenal medulla and the sympathetic system in fight-or-flight responses, but the adrenal medulla, in contrast to the cortex, is not essential for life. An intimate relation between the adrenal cortex and stress became evident from observations that stress from all kinds of challenges to homeostasis – cold, infection, inflammation, trauma, hypoglycemia, psychological shock, emotional distress, pain, heavy exercise, hemorrhage, and others – stimulates the secretion of adrenocortical hormones and causes hyperplasia of the adrenal cortex. Furthermore, Addisonian patients, adrenalectomized animals, and other adrenally insufficient organisms were the least capable of resisting the sometimes fatal onslaught of stress, but were protected by the administration of adrenocortical extracts.

At first the adrenal cortex was thought to regulate a multitude of effects on metabolism and salt and water balance, along with stress, through a single hormone. Eventually, two principal types of steroid hormones were identified, the GCs and the mineralocorticoids. Each was found to be essential for survival, the mineralocorticoids by controlling electrolyte and water balance, mainly via actions on the kidney, and the GCs by protecting against stress through mechanisms that were to remain obscure for decades. This article

discusses the mechanisms by which GCs protect against stress from a modern perspective.

Basal and Stress-Induced Glucocorticoid Levels: Functions in Stress?

As shown schematically in [Figure 1](#), basal levels of cortisol in humans and primates (and of corticosterone in rats and mice) vary in a characteristic circadian pattern, rising during sleep to a maximum at the start of the waking period and then subsiding during the active period. Superimposed on this periodicity are erratic spikes in cortisol levels caused by brief episodes of secretion. Stress at any time causes a rapid increase in GC secretion to peak GC levels that may be several times higher than those attained under basal conditions.

Here, we discuss the questions: What role do basal GC levels play in protecting the organism against stress? Is there some significance to the pattern of circadian variation? What role do stress-induced GC levels play? Tentative answers to these questions are already intimated in [Figure 1](#). Basal levels of GCs exert mainly permissive actions that prepare or prime some of the organism's homeostatic defense mechanisms for action, reaching a peak of preparedness as the diurnal activities begin. Stress-induced levels probably function mainly to suppress such defense mechanisms in order to prevent them from overshooting and damaging the organism. To answer the questions posed more completely, it is necessary first to survey some of the basic mechanisms and physiological consequences of GC actions.

Corticosteroid Receptors

The intracellular receptors for the GCs and mineralocorticoids, the GRs and MRs, respectively, were

Figure 1 Schematic depiction of diurnal variation of basal cortisol levels in humans and a stress-induced surge. Permissive and suppressive refer to the roles proposed for each of these glucocorticoid regimens in protecting against stress.

identified during the 1960s and cloned in the 1980s. GRs were characterized by their presence in GC target cells and their ability to specifically bind radioactively labeled cortisol and related GCs. MRs were characterized in mineralocorticoid target tissues by their ability to bind labeled aldosterone. Cortisol and corticosterone, the natural GCs, bind to GRs with dissociation constants in the range of normal GC concentrations in the blood. Similarly, aldosterone binds to MRs with a dissociation constant in the range of normal aldosterone concentrations in the blood, which are 100–1000 times lower than GC concentrations.

In the late 1980s, cortisol and corticosterone were found to bind to MRs with almost the same dissociation constant as aldosterone, that is, with a much higher affinity than to GRs. That posed a major quandary – because GCs would normally be expected to flood mineralocorticoid target cells and saturate MR binding sites, how does aldosterone bind to MRs? The quandary was resolved with the identification in mineralocorticoid target cells of the enzyme 11β -HSD2, which protects the MRs by rapidly inactivating GCs to their 11-keto forms, allowing aldosterone access to MRs. MRs in certain cells are unprotected by 11β -HSD2 and respond to GCs at concentrations far lower than those required to activate the GRs. Some cells in male and female reproductive tracts have 11β -HSD2 that may protect them from excessive levels of GCs.

The role of MRs as mediators of GC actions has been studied most extensively in the central nervous system. Both GRs and MRs are found in the brain and spinal cord, MRs being particularly abundant in the dentate gyrus and pyramidal cells of the hippocampus as well as other regions of the limbic system. There appears to be no 11β -HSD2 in the hippocampus, so hippocampal MRs are bound and activated mainly by GCs. Only the MRs in the anterior hypothalamus and circumventricular organs are protected by 11β -HSD2 and are therefore controlled by aldosterone. GRs are more widely dispersed in the central nervous system than MRs and are present in both neurons and glial cells.

GRs and MRs, when activated by hormone binding, initiate hormone actions by translocating to the nucleus and activating or repressing particular genes. Most GC and mineralocorticoid actions are thought to be produced through such genomic mechanisms, which are relatively slow, usually taking hours to become manifest. There is mounting evidence, however, that certain rapid effects of these and other steroid hormones, particularly in the nervous system, may be mediated by nongenomic effects transmitted through membrane receptors.

Permissive and Suppressive Glucocorticoid Actions

In the 1950s, Dwight Ingle found that adrenalectomized animals can respond normally to moderate stress if administered GCs at basal levels and concluded that, although stress-induced levels are required to protect against severe stress, they may not be necessary for moderate stress. He proposed that basal GC levels have permissive effects that are necessary for some homeostatic functions to respond to stress, distinguishing those effects from the regulatory effects of high GC levels espoused by Selye. Selye had introduced a unified theory of stress and proposed the controversial hypothesis that, by increasing levels of adrenocortical hormones, stress causes such diseases of adaptation as rheumatoid arthritis and allergy.

Permissive actions of the GCs on many defense mechanisms have since been found. They are generally produced by basal levels of GCs and often enhance the actions of such mediators of stress-induced responses as catecholamines and other stress hormones. Permissive actions thus occur during the unstressed periods indicated in [Figure 1](#) and can be regarded as preparing for a stressful episode. They can account for the substantially improved resistance to moderate stress of organisms lacking adrenocortical function, including Addisonian patients, when given maintenance levels of GCs. Among several mechanisms for permissive actions is the induction by the GCs of receptors for mediators of stress responses. Some other ways GCs are known to increase the sensitivity of signaling pathways are by strengthening coupling of a receptor to G-proteins and by increasing cAMP synthesis.

The suppressive actions of GCs are better known than the permissive actions. They have been extensively investigated because of their close link to the widespread clinical applications of GCs as immunosuppressants, as anti-inflammatory agents, and for treatment of lymphoproliferative diseases. For many years after they were described in 1949, the anti-inflammatory and immunosuppressive actions were regarded as the pharmacological effects of great therapeutic value but no physiological significance. Usually they are manifested at relatively high, stress-induced GC levels. They are exerted through many mechanisms; one mechanism that is fairly general is the suppression of cytokines and other mediators of stress responses.

Metabolic Actions

Early observations that GCs raise and maintain blood glucose levels gave the hormones their name. They also stimulate hepatic glycogen deposition. Long,

Katzin, and Fry, in a classic 1940 paper, showed that GCs stimulate gluconeogenesis from amino acids derived from protein catabolism and decrease glucose oxidation. Ingle later found that GCs decrease glucose use and cause insulin resistance. Much work since then has elucidated some of the molecular mechanisms of these and other actions. In the case of gluconeogenesis, there is increased activity of phosphoenolpyruvate carboxykinase and other rate-limiting enzymes. The inhibition of glucose transport and insulin resistance are due to decreased translocation of glucose transporters to the cell membrane and decreased synthesis of insulin receptor substrate-1 (IRS-1). Liver glycogen is increased partly in response to the activation of glycogen synthase. Selye suggested that GCs protect against stress by providing an increased need for glucose. This idea did not survive experimental tests, which showed that glucose alone cannot substitute for GCs.

GCs are permissive for gluconeogenesis and glycolysis stimulated by catecholamines and glucagon, reactions that respond to stress in a fight-or-flight situation as well as to insulin-induced hypoglycemia. GC induction of glycogen synthesis can be regarded as a preparative action that anticipates future stressful episodes.

How GC actions on carbohydrate metabolism protect the organism may be viewed in two distinct ways. The ethological view, which considers how evolutionary pressures have molded GC actions for the survival of, for example, a confrontation between predator and prey, emphasizes the permissive role of GCs in acutely raising blood glucose levels to fuel muscular activity. The metabolic view, on the other hand, sees GCs, through their anti-insulin and permissive actions, as protecting the organism from insulin-induced hypoglycemia, as can occur after a meal. GCs share this role with other counterregulatory hormones, catecholamines and glucagon.

Cardiovascular Actions

It has long been known that Addisonian patients, adrenalectomized animals, and other organisms deficient in GCs or GC activity are relatively insensitive to the actions of vasoactive agents such as norepinephrine, vasopressin, and angiotensin II. GCs at basal levels permissively enhance that sensitivity in both vascular and cardiac tissues. These actions may be due partly to the enhancement of α_1 B and β_2 catecholamine receptors and angiotensin II type 1 receptors in smooth muscle cells, as well as increased sensitivity of the G-protein-coupling receptor and adenylyl cyclase. GCs also increase cardiac output, which may be related to induction in cardiocytes of Na,K-ATPase.

Despite evidence that GCs suppress catecholamine release, which counters the permissive actions, permissive enhancement clearly predominates in the cardiovascular stress response.

Actions on Electrolyte and Fluid Volume Balance

GC deficiency is associated with decreased ability to excrete water, which at one time was used as a test for GC insufficiency. It appears to be due to a decreased rate in glomerular filtration and an increased synthesis of vasopressin (VP), both of which are reversed by administered GCs. The underlying mechanisms are not known, but they may be related to the glucocorticoid-induced synthesis and secretion of atrial natriuretic peptide (ANP) and increased levels of ANP receptors on endothelial cells. The inhibition of VP synthesis is part of the negative feedback mechanism by which GCs regulate their own concentration and appears to be due to the decreased synthesis of VP.

Some of these actions are central to the role of GCs in stress. In rats, the stress of hemorrhage has been found to elicit a powerful vasoconstrictor response from VP, catecholamines, and renin. Without GCs, the VP response can overshoot, leading to ischemia and death in adrenalectomized animals. Stress-induced GCs protect the organism by limiting the increase in VP levels and hence the ischemia.

Anti-inflammatory and Immunosuppressive Actions

High levels of GCs suppress many functions. The inflammatory and immune systems are among those in which suppressive actions are most pronounced. Thymus enlargement in the absence of the adrenal cortex was recognized before 1900. Selye showed that stress causes thymus atrophy, a GC action now known to be due to the induction of lymphocyte apoptosis.

The anti-inflammatory actions of GCs, which account for most clinical applications of these hormones, were reported in 1949 by Hench, Kendall, Slocumb, and Polley, who found that treatment with GCs dramatically improved the symptoms of patients with rheumatoid arthritis. These observations had two unexpected consequences: (1) they contradicted Selye's hypothesis of diseases of adaptation, which rapidly lost support, and (2) GC physiologists were unable to reconcile the finding that GCs suppressed a defense mechanism, in this case inflammation, with their longstanding belief that stress-induced GC levels helped resist stress by enhancing activity of defense mechanisms. Despite an alternative view proposed by Marius Tausk (in a 1951 review that unfortunately had very

limited circulation), physiologists categorized the anti-inflammatory actions as the pharmacological consequences of high unphysiological levels of GCs. The closely related immunosuppressive actions suffered the same fate. As a result, the spectacular development of new applications and synthetic analogs for GCs, the miracle drugs of the 1950s, proceeded with little or no involvement by GC physiologists.

The view advanced in germinal form by Marius Tausk in the context of GC therapy was revived independently in 1984 in the context of GC physiology. It held that the anti-inflammatory and immunosuppressive actions of GCs, far from being pharmacological, are prototypes for the physiological role of stress-induced GCs in stress – that role is to prevent stress-induced defense reactions from overshooting and harming the organism.

A great deal of evidence now supports the view that anti-inflammatory and immunosuppressive actions are physiological and are exerted by endogenous GCs. In rats, for example, adrenalectomy or administration of the glucocorticoid antagonist RU486 increases inflammatory responses, showing that endogenous GCs can control inflammation. Autoimmune reactions are also under the control of endogenous GCs. Striking experiments have shown that Lewis rats, which are extremely sensitive to arthritis after injection with streptococcal cell wall polysaccharide (SCW) and to experimental allergic encephalomyelitis (EAE) after injection with myelin basic protein, have a defect in biosynthesis of corticotropin releasing hormone (CRH), the hypothalamic hormone that, along with VP stimulates ACTH, is released by the pituitary. That defect reduces the ACTH, and hence the GC, response to an antigenic challenge. As expected, treatment with GCs protects Lewis rats from SCW.

GCs may also influence immune responses through permissive actions. For example, mitogenic responses of rat peripheral or splenic T cells in culture are reduced if the rats have been adrenalectomized. The responses can be restored by treating the rats with low physiological doses of corticosterone, as well as by brief exposure of the cells to low concentrations of corticosterone or aldosterone. These observations led to the suggestion that the permissive effects in this case were mediated by MRs, and possibly involve induction of interleukin (IL)-2 receptors. The acute phase response is a case in which GCs both potentiate the induction of acute phase proteins by cytokines such as IL-1 and IL-6 and suppress the production of the cytokines.

The permissive actions of GCs at stress-induced levels were revealed by experiments in which normal humans were given an endotoxin to stimulate increases in plasma tumor necrosis factor (TNF)- α and IL-6. At

various times before or after the endotoxin, cortisol was infused at rates that gave stress-induced levels. When given within 6 h of the endotoxin, cortisol suppressed the cytokine response, but, when given 12, 32, 72, or 144 h before endotoxin, cortisol markedly enhanced the response.

Actions on the Central Nervous System

Electrophysiological experiments have been conducted with hippocampal tissue isolated from adrenalectomized rats and treated with GCs at various concentrations. Low concentrations of corticosterone, which mainly activate the MRs, were found to decrease after hyperpolarization of the neuronal membranes and enhance neuronal excitability, whereas high concentrations of corticosterone, or specific glucocorticoid agonists that activate the GRs but not MRs, suppressed excitability. Thus, GCs at low concentrations, corresponding to basal levels, permissively maintain neuronal excitability via the MRs, whereas GCs at high concentrations, corresponding to stress-induced levels, suppress stimulated neuronal activity via the GRs.

Effects via Cytokines and Other Mediators

As already indicated, suppressive actions of GCs are often due to the inhibition of production or activity of cytokines, the hormones of the immune system, and of other mediators. Such mediators constitute a communications network between cells of defense systems that respond to stress-induced challenges. Stress-induced mediators known to be suppressed by GCs are listed in [Table 1](#). Neurotransmitters, such as the catecholamines, respond to sudden fight-or-flight challenges; inflammatory agents respond to tissue damage; cytokines and chemokines respond to infection and inflammation; and so on. Mediators are essential for propagating stress responses. By blocking them, GCs can dampen the stress responses, preventing them from overshooting and damaging the organism. At the same time, GCs also protect the organism from toxicity of most of these mediators when they are present in excess.

Many well-known GC effects on cell traffic may be initiated through the inhibition of chemokines (also known as chemotactic cytokines), which regulate the traffic and homing of leukocytes by binding to cell-surface receptors and which are actively secreted during inflammation. Some mediators are suppressed by GCs under some conditions and stimulated under others. There are also mediators, such as macrophage colony stimulating factor (M-CSF), that appear not to be affected by GCs at all.

Table 1 Effects of glucocorticoids on mediators and mediator receptors^a

	Mediators suppressed	Mediators suppressed/ stimulated ^b	Mediator receptors induced
Cytokines	IL-1, IL-2, IL-3, IL-5, IL-6, IL-11, IL-12, IL-16, IFN- γ , TNF- α , GM-CSF	IL-4, IL-10, TGF- β	IL-1, IL-2, IL-4, IL-6, IFN- γ , GM-CSF
Chemokines	IL-8, MCP-1, RANTES, MIP-1 α , CINC/gro, LIX, SCF		
Inflammatory agents	5-HT, bradykinin, histamine, eicosanoids, Cox-2, collagenase, elastase, MMP-9, plasminogen activator		5-HT
Hormones and neurotransmitters	ACTH, CRH, VP, oxytocin, β -endorphin, LH, insulin, norepinephrine, nitric oxide, substance P	Epinephrine	CRH, VP, insulin, norepinephrine
Cell adhesion molecules	ICAM-1, LFA-1, e-selectin ELAM-1		

^a5-HT, serotonin; ACTH, adrenocorticotrophic hormone; CINC/gro, cytokine-induced neutrophil chemoattractant/growth-induced gene product; Cox, cyclo-oxygenase; CRH, corticotropin releasing hormone; ELAM, endothelial-leukocyte adhesion molecule; GM-CSF, granulocyte macrophage colony stimulating factor; ICAM, intercellular adhesion molecule; IFN, interferon; IL, interleukin; LFA, lymphocyte function-associated antigen; LIX, lipopolysaccharide-induced CXC chemokine; MCP, monocyte chemoattractant protein; MIP, macrophage inflammatory protein; MMP, matrix metalloproteinase; RANTES, regulated on activation, normal T-cell-expressed and secreted; SCF, stem-cell factor; TGF, tumor growth factor; TNF, tumor necrosis factor; VP, vasopressin.

^bMediators suppressed by GCs under some conditions and stimulated under others.

Table 1 lists several mediators that have receptors that are induced by GCs. The possibility that the induction of mediator receptors accounts for some permissive actions has already been noted. Some cytokines, such as IL-1 and IL-6, not only communicate between cells of the immune and inflammatory systems, but also, as first proposed by Besedovsky and Sorkin, may signal the HPA system that the immune system is activated, thereby constituting a negative feedback loop through which GCs are summoned to control activated immune reactions.

Unified View of the Protective Roles of Glucocorticoids in Stress

As described so far, GCs exert actions that are predominantly permissive on the cardiovascular system; that are mainly suppressive on other systems, such as inflammation; and that are both permissive and suppressive on still other systems, such as the neural and immune systems. How are these opposing influences reconciled when both are present, with one enhancing and the other suppressing the defense response? This question can be analyzed with a simple but fairly realistic model in which suppressive actions are assumed to be due to the reduction in the concentration of a mediator and permissive actions are due to the induction of the mediator's receptors, as illustrated in **Figure 2**.

In **Figure 2**, a lymphokine receptor (R) is permissively induced by cortisol over a concentration range corresponding roughly to that in **Figure 1** (keeping in mind that at low cortisol concentrations less than 10% of total cortisol is free), following a

Figure 2 Model of a cortisol-regulated lymphokine system. Cortisol is assumed to permissively increase the concentration of lymphokine receptors (R) and to suppress the concentration of the lymphokine (L), according to dose-response curves that correspond to binding of cortisol to GRs with a dissociation constant of 30 nM. The concentration and activity of the lymphokine-receptor complex (LR) is determined by the equations in the inset, yielding the bell-shaped curve with a rising permissive branch at basal cortisol concentrations and a falling suppressive branch at stress-induced concentrations. Brackets denote concentration. Below the cortisol concentration scale the ranges covered during basal diurnal variation and stress are indicated roughly.

dose-response curve chosen to parallel the binding of cortisol to GRs. Lymphokine (L) is suppressed according to an identical dose-response curve of opposite sign. Through these actions, cortisol regulates the concentration of the lymphokine-receptor complex (LR), as determined by the equations in the inset. The bell-shaped curve for LR and LR activity is, then, a composite dose-response curve that represents

schematically the outcome of permissive and suppressive GC actions on the hypothetical defense mechanism that the lymphokine regulates (the simple curves for R and L represent the outcome for defense mechanisms subject to pure permissive and suppressive actions, respectively).

This model assumes that both permissive and suppressive actions are mediated by GRs. If permissive actions were mediated by MRs, the dose-response curve for induction of R and the ascending limb of the bell-shaped curve would be shifted to the left, as would the peak of the bell-shaped curve; similar qualitative conclusions would apply, however.

It should be evident that any permissive and suppressive actions with roughly comparable dose-response curves, whether transmitted via a lymphokine or other mechanism, will yield similar bell-shaped curves. Such curves correspond well with the physiological roles of GCs we have sketched earlier. Basal GC concentrations fluctuate during normal diurnal variation from the left end of the cortisol scale in [Figure 2](#) to approximately where the bell-shaped curve peaks and can be viewed as permissively priming some of the organism's defense mechanisms in preparation for a period of activity. Suppressive actions are present at all cortisol concentrations, but they predominate only at high stress-induced levels toward the right end of the cortisol scale, where they are required to prevent defense mechanisms from overshooting. In the absence of GCs, an organism may succumb to stress either because its defense mechanisms are not adequately primed (perhaps what happens in Addisonian crisis if the cardiovascular system cannot respond) or because the defense mechanisms overshoot (as occurred in the examples cited earlier after hemorrhage or an inflammatory challenge), depending on the nature of the stressor.

Thus, in summary, GCs can be thought of as protecting the organism from stress through two separate but related mechanisms. First, they are essential before a stressful episode to permissively prime certain defense mechanisms, a task generally accomplished by basal GC levels. Second, they are essential after a stressor to prevent some defense mechanisms from

overshooting, a task generally requiring stress-induced GC levels.

Sites of Production and Pathways

Biochemical Actions and Physiological Functions

Glossary

*Adenylyl
cyclase-cyclic
adenosine
monophos-
phate (cAMP)
system*

An important component of a common signal transduction system that generates cAMP from adenosine triphosphate (ATP) following the activation of the membrane-bound enzymes adenylyl cyclases. The latter is triggered by subunits of G-proteins that are activated by receptors belonging to the superfamily of seven membrane-spanning receptors. The augmented level of intracellular cAMP in turn activates protein kinase A, which phosphorylates proteins to accomplish important cell functions.

G-proteins

A superfamily of proteins that act as intermediates between seven membrane-spanning receptors and membrane-bound enzymes to generate biochemical signals. Following activation by the receptors, the subunits of G-proteins augment or suppress the activity of adenylyl cyclases, phospholipase C, and ion channels through direct bindings to these proteins to modulate their functions.

*Hypophy-
siotropic
hormones*

Small proteins or peptides produced in cell bodies of hypothalamic neurons and transported along axons to the external layer of median eminence. The peptides are considered neurohormones because they are released into portal blood to modulate the functions of various types of pituitary cells. These neurohormones include corticotropin releasing hormone, growth hormone releasing hormone, luteinizing hormone releasing hormone, thyrotropin releasing hormone, and somatostatin.

*In situ
hybridization*

A method commonly used to identify sites of protein or peptide production at cellular level by demonstrating the

presence of corresponding mRNA signals. Specific mRNA signals on fixed tissue sections or cultured cells are detected by cross-binding with short sequence of radioactive or labeled nucleotides complementary to the equivalent part on the mRNA of interest.

Portal blood

The pool of blood that flows from the median eminence of the hypothalamus toward the pituitary gland. It carries hypophysiotropic neurohormones released from the median eminence to act on receptors in various cell types of the anterior pituitary.

*Radioimmuno-
assay*

A sensitive technique particularly useful for measuring small quantities of peptides in picogram concentrations. It is performed by first raising antibodies against peptides or antigens of interest. Displacement of the bound radioactive antigens or peptides from the antibodies by standard amounts of unlabeled antigen or synthetic peptides is established. By comparison to the standard displacement curve, the unknown quantity of the peptide is estimated by calculating the extent of its displacement of the labeled peptide from the antibodies.

The term corticotropin releasing hormone (CRH) was first coined about 40 years ago to describe a hypothalamic derivative that explicitly induces the release of pituitary adrenocorticotrophic hormone (ACTH). In 1981, the 41-amino-acid sequence of CRH was characterized by Vale and his colleagues at the Salk Institute. The neuropeptide has satisfied all the requirements as a hypophysiotropic hormone that specifically activates pituitary corticotrophs to augment the production of proopiomelanocortin (POMC), the precursor of ACTH, and the release of ACTH.

Structure and Gene

CRH(human, rat): Ser-Glu-Glu-Pro-Pro-Ile-Ser-Leu-Asp-Leu-Thr-Phe-His-Leu-Leu-Arg-Glu-Val-Leu-Glu-Met-Ala-Arg-Ala-Glu-Gln-Leu-Ala-Gln-Gln-Ala-His-Ser-Asn-Arg-Lys-Leu-Met-Glu-Ile-Ile-NH₂ (molecular weight, MW, 4758.1).

The sequence of CRH is highly preserved across species. In the case of humans and rats, they are identical and share greater than 90% homology when compared to that of monkeys and sheep.

The C-terminus of CRH-41 is critical for biological activity and the minimal sequence that retains full CRH activity in the rat species is 15–41. The shorter peptide has a much higher median effective dose (ED_{50}) than CRH-41 because of its lower affinity to the receptors. Whereas the C-terminal truncated peptide CRH(9–41) in α -helix conformation acts as an antagonist to type I CRH receptors, human CRH(6–33) and CRH(9–33) do not possess biological activities but bind strongly to CRH-binding proteins. The amino acid sequence of CRH shares a structure similarity of greater than 40% with urocortin, amphibian sauvagine, and fish urotensin I, all of which are biologically active in releasing ACTH from pituitary corticotrophs.

The human and rat CRH genes share great similarity; they both contain two exons separated by an intervening sequence. The first exon contains approximately 10 bp of the 5' untranslated region of the mRNA. The second exon contains 15 bp of the 5' untranslated region of the mRNA, the protein coding region, and the complete 3' untranslated region of the mRNA. The two genes are very homologous, suggesting that it has been highly conserved through evolution. The DNA sequence encoding the CRH protein shows a 94% homology, and the homology decreases to 80% for the rest of the CRH precursor. Similarly, a greater than 90% homology between humans and rats is also found in 5' flanking DNA sequences representing DNA regulatory elements for CRH gene regulation. In this region, there are consensus sequences putative for interactions with transcription proteins mediating the biochemical effects of glucocorticoids and derivatives from protein kinase A and protein kinase C activities.

Sites of Production and Pathways

In the brain, CRH is produced predominantly in the parvocellular subdivision of paraventricular nuclei (PVN) of the hypothalamus. These CRH-producing cells are hypophysiotropic and are involved in the regulation of pituitary corticotrophs because approximately 90% of the cells send their axons to the external layer of the median eminence (ME). From this pathway, CRH-41 is released into the portal blood to act on pituitary corticotrophs. Another CRH-41 pathway reaches the ME from magnocellular neurons of the PVN and the supraoptic and the accessory magnocellular nuclei of the hypothalamus. This pathway contains low levels of CRH-41, perhaps 10% of the amount found in the parvocellular pathway, and the neuropeptide comes predominantly from oxytocinergic magnocellular neurons and the neurites project mainly to the neural lobe of the pituitary.

A substantial proportion of CRH-producing neurons in the PVN are capable of expressing arginine vasopressin (AVP). Prominent expression of the AVP mRNA signal, as determined by *in situ* hybridization of AVP peptides by immunohistochemistry, has been demonstrated in CRH neurons after the removal of circulating glucocorticoids by adrenalectomy. In adrenalectomized rats, there is a concurrent increase in the production of the two neurohormones in CRH neurons and in their release into portal blood, as confirmed by radioimmunoassay. CRH and AVP act synergistically and induce a marked augmentation of pituitary POMC synthesis and ACTH release from pituitary corticotrophs. Although the physiological significance of this biological process remains unclear, it may act as a safety measure to enable pituitary ACTH to rapidly increase circulating glucocorticoids when the adrenal steroids reach a low level.

CRH-containing neurons are also present in the hippocampus, amygdala, and cortex. Although CRH axons from these sites do not project to the ME, they show synaptic formations in regions that are rich in CRH type I receptors and may be involved in modulating anxiety, cognition, and memory. This is in contrast to the distribution of CRH type II receptors, which correlates better with that of the axonal terminals of urocortin-producing neurons. Unlike CRH, hypothalamic or central urocortin neurons do not take part in the regulation of pituitary corticotrophs.

CRH-41 and its receptors are also found in cells intrinsic to spinal cord, peripheral lymphoid organs, gonads, placental endometrium, and adrenal glands. In these tissues, the peptides are likely to play a paracrine role by modulating the functions of adjacent cells or blood vessels in the same tissues. In some of these organs, CRH is known to induce vascular relaxation and involves in inflammatory responses. It is of interest to note that, whereas the CRH mRNA species of the rat hypothalamus is approximately 1400 bases, those found in the adrenal and gonads of the same species are larger by approximately 200 and 500 bases. These additional lengths of base pairs are found mainly at the nontranslated sites of the mRNA.

Biochemical Actions and Physiological Functions

Hypothalamic CRH is the principal hypophysiotropic activator of pituitary corticotrophs for the release of ACTH. Circulating ACTH, in turn, augments the synthesis and the release of corticosteroids from adrenal glands. In addition to exerting biochemical actions on the brain and peripheral tissues involved in stress response, one of the important roles of corticosteroids is to produce a negative feedback to dampen

the activity of hypothalamic CRH neurons and pituitary corticotrophs. These hierarchical levels of interactions and the negative feedback loop of circulating adrenoglucocorticoids form the basis of the stress circuit commonly known as the hypothalamic-pituitary-adrenal (HPA) axis.

The biochemical effect of CRH on corticotrophs is mediated through the activation of type I CRH receptors (CRH-RI) in corticotrophs of the anterior pituitary and intermediate lobe. The receptor is a 415-amino-acid protein comprising seven membrane-spanning domains. It belongs to the superfamily of G-protein-coupled receptors and is also activated by urocotin, urotensin, and sauvagine.

CRH binds to the receptors with high specificity and affinity with a K_d in the nanomolar range. Following its activation, the receptor couples GTP-binding proteins to effector enzymes, adenylyl cyclases that produce intracellular cAMP. The latter acts on protein kinase A to augment POMC mRNA expression and the release of ACTH. Consequently, derivatives of cAMP and agents that increase the intracellular levels of this second messenger (e.g., forskolin) mimic the effects of CRH-41 in all respects, whereas the inhibitor of cAMP-dependent kinase blocks the stimulating effects of CRH-41.

In addition to acting on the adenylyl cyclase-cAMP system, CRH-41 also increases the level of cytosolic free calcium through facilitating the influx of calcium from the extracellular medium. In addition, CRH-41 activates pathways related to arachidonic acid metabolism and produces metabolites that may stimulate or inhibit ACTH secretion.

Interaction with Arginine Vasopressin

Whereas AVP also stimulates the release of ACTH, the action of AVP is mediated through V3 receptors in the pituitary corticotrophs. The V3 receptors belong to the G-protein-coupling receptor superfamily, but the receptor acts by triggering membrane-bound phospholipase C to increase the turnover of inositol phosphate and diacylglycerol. This biological process is markedly different from that of CRH-41 because it results in enhancing protein kinase C activity. Hence, the stimulating effect of AVP synergizes with the action of CRH-41 in amplifying ACTH release by two- to threefold through the interaction of protein kinase A- and protein kinase C-dependent pathways.

In addition to AVP, there are other peptides and neurotransmitters that are also capable of stimulating the release of ACTH in a less efficient manner than CRH. The effects of these compounds on ACTH release in general are additive to CRH-41. These include oxytocin, angiotensin II and cholecystokinin,

noradrenaline, and adrenaline. On the other hand, a truncated form of atrial natriuretic peptide (ANP (5–28)) of hypothalamic origin, which is released into the portal blood, inhibits the baseline CRH-stimulated expression of POMC mRNA and the release of ACTH.

Effects of Corticotropin Releasing Hormone in the Brain

In addition to modulating pituitary corticotrophs, CRH-41 also acts on the central nervous system through two receptors: CRH-RI and CRH-RII. The CRH-RII has 431 amino acids and shares a 68% similarity with its counterpart. The CRH-RI is found in forebrain with a widespread signal throughout all areas of the neo-, olfactory, and hippocampal cortices. It is also present in subcortical limbic structures, in the septal region, and amygdala; low levels are seen in ventral thalamic and medial hypothalamic nuclei. In brain stem, high levels of receptors are found, including in the cerebellar and deep nuclei and precerebellar nuclei. The CRH-RI has been implicated in mediating behavioral changes associated with anxiety and the development of a functional HPA axis. CRH-41 has also been implicated as playing an important role in augmenting the central sympathetic system, involving in the modulation of the central cardiovascular system. On the other hand, CRH-41 suppresses growth and the reproductive system by inhibiting the release of growth hormone releasing hormone and luteinizing hormone releasing hormone at the hypothalamic level.

Glossary

<i>Corticotropes</i>	Endocrine cells in the anterior pituitary that release adrenocorticotrophic hormone into the bloodstream.
<i>Corticotropin releasing factor (CRF) family</i>	A family of peptide ligands that bind CRF receptors; they were identified based on homology to CRF.
<i>CRF receptor-deficient mice</i>	The mice resulting from genetic manipulation of DNA to remove the genes encoding CRF receptors.
<i>CRF receptors</i>	Two seven-transmembrane G-protein-coupled receptors that are bound and activated by CRF family peptide ligands.
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	The neuroendocrine circuit that coordinates the release of corticosteroids into the bloodstream in response to stress.

Paraventricular nucleus of the hypothalamus (PVN)

A nucleus in the hypothalamus containing neurons that release factors into portal circulation, which then stimulate the release of hormones from the anterior pituitary into the bloodstream.

Stress response

The cumulative physiological and behavioral response to real or perceived threats to homeostasis.

Corticotropin releasing factor (CRF) is released from the paraventricular nucleus of the hypothalamus (PVN) into the portal circulation in response to stress. In the anterior pituitary, CRF receptors on pituitary corticotropes respond to CRF by releasing adrenocorticotrophic hormone (ACTH), which circulates in the bloodstream and, in turn, causes the release of glucocorticoids from the adrenal cortex. These corticosteroids are the primary effectors of the hypothalamic-pituitary-adrenal (HPA) axis stress response. CRF and its family of peptide ligands are also released at many other sites in the brain and in the periphery, where they effect cellular and physiological changes in addition to the activation of the HPA axis. The nature of these changes is determined by where CRF and related ligands bind and activate CRF receptors. Loss-of-function studies in mice deficient for CRF receptors have confirmed the importance of these receptors in bringing about corticosteroid release and have provided evidence for additional roles of CRF receptors in modulating the amplitude, duration, and behavioral outcome of the stress response. Here, we review what these receptor-deficient mice have taught us about how CRF receptors function to mediate and modulate stress.

Corticotropin Releasing Factor Receptors and Ligands

Two receptors for CRF have been identified. CRF type 1 receptor (CRFR1) is a high-affinity receptor for CRF that mediates the response of anterior pituitary corticotropes to CRF. CRF type 2 receptor (CRFR2), which shares 70% amino acid identity with CRFR1, has a lower affinity for CRF than the other CRF family peptide ligands. Urocortin (UCN1), a peptide ligand with homology to CRF, binds both CRFR1 and CRFR2 with high affinity, whereas urocortin 2 (UCN2) and urocortin 3 (UCN3) bind only CRFR2 with high affinity. Each peptide ligand has a unique distribution in the brain and peripheral tissues and overlaps in distinct areas with CRFR1 and CRFR2. For example, CRFR1 is expressed in the anterior pituitary, where it responds to CRF release from the PVN. In contrast, CRFR2 is expressed in the lateral septum, where it most likely responds to UCN1 from the Edinger–Westphal nucleus and UCN3 from the paraventricular region of the hypothalamus. The discrete localization of each unique receptor–ligand pair suggests a distinct role for each receptor in the stress response. By selectively removing these genes from mice, we have begun to understand these roles.

CRFR1-Deficient Mice Have a Defective Hypothalamic–Pituitary–Adrenal Axis Response to Stress

CRFR1-deficient mice display abnormally low levels of circulating corticosteroids. This can be explained by a lack of responsiveness of anterior pituitary cells to CRF. The inability to stimulate ACTH release, which then activates corticosteroid release, not only blunts the stress response but also prevents the proper development of the adrenal cortex. The ACTH-responsive zona fasciculata of the adrenal gland fails to develop appropriately and undergoes atrophy in CRFR1-deficient animals. The supplementation of ACTH in postnatal animals (postnatal day 10 to postnatal day 21) can rescue adrenal gland development, indicating that an early postnatal CRFR1-dependent release of ACTH is necessary for proper adrenal gland development. The combination of adrenal gland atrophy and reduced ACTH release from the pituitary results in a profoundly reduced corticosteroid release in response to stress. Consistent with the notion that CRF and CRFR1 function as a ligand–receptor pair, this CRFR1-deficient phenotype mirrors the phenotype observed in CRF-deficient mice.

In addition to having a defective HPA axis, CRFR1-deficient animals display reduced anxiety-like behavior. In the elevated plus-maze and in the

dark–light emergence task, two well-defined behavioral paradigms that measure anxiety-related behavior, CRFR1-deficient animals display decreased anxiety. This could be due to a blunted HPA response in mutant animals or a function of CRFR1 at other sites in the nervous system. To distinguish between these possibilities, investigators provided exogenous corticosteroids, which failed to rescue the anxiety-like behavioral phenotype. These data suggest that CRFR1 might modulate stress-induced behavior through actions in the brain, independent of HPA axis stimulation. Indeed, data from a forebrain-specific CRFR1-deficient animal support this interpretation. In the forebrain-specific loss of function, the pituitary retains expression of CRFR1. These animals have normal resting ACTH and corticosteroid levels as well as an intact HPA response. However, they display a reduction in anxiety-related behavior similar to full animal CRFR1-deficiency. Together, these findings strongly suggest that CRFR1 is involved in generating anxiety-like behavior through action in the forebrain, independent of its role in activating the HPA axis in the pituitary.

CRFR2-Deficient Mice Are Hypersensitive to Stress

In contrast to CRFR1-deficient mice, CRFR2-deficient mice display a hyperactive HPA axis and increased anxiety-like behavior. ACTH levels in CRFR2-deficient mice rise to approximately twice that of wild-type littermates following 2 min of restraint stress. Corticosteroid levels also remain elevated for a longer period of time following stress in the CRFR2 mutants. Consistent with overactive HPA axis dynamics, CRFR2-deficient animals appear more anxious than their wild-type littermates. In the elevated plus-maze and open field test, CRFR2-deficient mice display increased anxiety-like behavior. This might be due to a lack of modulation of the HPA axis, which is normally provided by CRFR2. Alternatively, it could be due to independent functions of CRFR2 apart from the regulation of the HPA axis.

CRFR2 is the most widely expressed CRF receptor in peripheral tissues. It was discovered based on its high levels of expression in the heart and skeletal muscle. Recently, additional functions for CRFR2 have been suggested by peripheral phenotypes observed in the CRFR2-deficient animal. For example, CRFR2-deficient animals have elevated blood pressure and fail to respond to UCN1 with an increase in heart contractility. In addition, an increase in temperature of the interscapular brown adipose tissue of CRFR2-deficient animals has been

reported, suggesting metabolic abnormalities. Consistently, these animals consume more food and gain less body fat when fed a high fat diet. These findings highlight the importance of CRF receptors in mediating peripheral changes in response to stress as well as central nervous system and neuroendocrine stress responses.

UCN1-Deficient Mice Have Increased Anxiety and Hearing Impairment

In order to gain more insight into the CRFR2-deficient mouse phenotype, a UCN1-deficient mouse has been generated. Interestingly, UCN1-deficient animals display increased anxiety-like behavior, similar to the CRFR2-deficient animal. Indeed, when the investigators examined CRFR2 expression in the lateral septum, where UCN1 projections meet CRFR2-expressing neurons, they saw greatly reduced levels of CRFR2 expression. This finding is consistent with a role for UCN1/CRFR2 in the lateral septum to control anxiety-related behavior. This control, however, must be independent of the modulation of the HPA by CRFR2 because the UCN1-deficient animal displays no changes in the dynamics of HPA function. This suggests that the role played by CRFR2 in regulating the HPA is either independent of UCN1 or that other ligands for CRFR2 function redundantly in the absence of UCN1.

An additional phenotype observed in the UCN1 knockout mouse is hearing impairment. UCN1-deficient mice showed an approximately twofold increase

in the threshold for reaction to an auditory stimulus compared with wild-type mice. Although a role for UCN1 in development of the auditory system was not expected, it is consistent with CRFR1 and CRFR2 expression in the organ of Corti. Moreover, UCN1 is expressed on fibers of the lateral superior olive that project to the inner hair cells of the organ of Corti. Curiously, the change in auditory threshold indicates a problem with the outer hair cells. The investigators hypothesize that UCN1 from the inner hair cells is involved in a paracrine signal to the outer hair cells, which is required during development of the organ.

CRFR1/CRFR2-Double-Deficient Animals Have a Blunted Hypothalamic-Pituitary-Adrenal Axis Stress Response

The CRFR1-deficient mouse has an impaired HPA axis and displays decreased anxiety-like behavior, whereas the CRFR2-deficient mouse has a hypersensitive HPA axis and increased anxiety-like behavior. How do mice deficient for both CRFR1 and CRFR2 respond to stress? CRFR1-CRFR2-deficient mice have a decreased HPA response and decreased anxiety-related behavior, displaying a very similar phenotype to CRFR1-deficient animals. This suggests that the deletion of CRFR1 has a dominant impact on behavioral phenotypes associated with loss of CRF receptors, whereas CRFR2 most likely modulates behavior through central nervous system actions. The central functions of CRFR1 and CRFR2 can affect the HPA axis by changing neural activity in the PVN.

Table 1 CRF receptor- and ligand-deficient mouse phenotypes

Genotype	HPA function	Anxiety-related behavior	Peripheral tissue development/function	Source ^a
CRFR1-deficient	Inactive	Decreased anxiety	Abnormal adrenal cortex development	6, 7
CRFR2-deficient	Hyperactive	Increased anxiety	Altered cardiac function, altered metabolism	1, 2, 3, 4
CRF-deficient	Inactive	Not reported	Abnormal adrenal cortex development	5
UCN1-deficient	Normal	Increased anxiety	Hearing impairment	8

CRFR1 activates the PVN, whereas CRFR2 might decrease activity in the PVN to modulate HPA dynamics. The modulations made by central actions of CRFR1 and CRFR2, however, cannot override the changes in behavior that result from a defective HPA due to CRFR1 deficiency. Research is in progress to further understand how the complex actions of these receptor systems in the brain coordinate with the HPA axis to influence behavior.

Conclusion

CRFR1- and CRFR2-deficient mice have improved our understanding of the prominent roles these receptors play in the stress response. CRFR1 functions to activate the HPA axis and generate anxious behavior. Within the HPA axis, CRFR2 functions to control overactivity. In addition, CRFR1 and CRFR2 act within the central nervous system to influence behavior. CRFR2 also acts in the periphery to alter metabolism and cardiac function. UCN1 has an unexpected role in the development of the auditory system (Table 1). The diverse effects of CRF receptor deficiency on HPA axis, central nervous system, and peripheral tissue functions demonstrate the important contributions of CRF and its family of peptide ligands to adaptive responses to stress.

Role of Corticotropin Releasing Hormone-Binding Protein in the Stress Response

Glossary

Corticotropin releasing factor (CRF)

A hypothalamic peptide comprising 41 amino acid residues that is secreted in response to stressful stimuli into the hypothalamic-pituitary portal system causing release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland.

Corticotropin releasing factor-binding protein (CRF-BP)

A 37-kDa protein that binds CRF and is found in the circulation of higher primates as well as, in both membrane-bound and free forms, in the brain of all vertebrates hitherto examined.

Introduction

Under experimental conditions, the corticotropin releasing hormone-binding protein (CRF-BP) is able to bind CRF and render it biologically inactive. Because CRF-BP expression overlaps with CRF receptor expression in several areas of the brain, including the pituitary gland, it has been postulated that its function is to modulate the neuroendocrine and transmitter activities of CRF. The presence of CRF-BP in the periphery of higher primates as well indicates that this protein is involved in modulating the action of CRF in the periphery, where CRF has known proinflammatory effects (this is in contrast to the centrally derived anti-inflammatory action of CRF via the release of cortisol). Thus, the CRF-BP may play a pivotal role in the crossover of endocrine, immune, and higher functions in both acute and chronic stress responses.

Distribution

Central Corticotropin Releasing Factor-Binding Protein

From histochemistry and *in situ* hybridization, membrane-bound CRF-BP is observed to be expressed in the rat brain predominantly in the cerebral cortex, including archipaleo- and neocortical fields (see [Figure 1](#)). It is present also in subcortical limbic structures (amygdala and bed of the stria terminalis) and sensory relays of the auditory, olfactory, vestibular, and trigeminal systems; several raphe nuclei; and some cell groups of the brain stem reticular core. Hypothalamic expression occurs only in the ventral premammillary and dorsomedial nuclei. It is expressed in both neurons and glial astrocytes as well as in pituitary corticotrophs. Its wide distribution does not consistently match the more limited distribution of CRF, and the expression of the CRF 1 receptor (CRF-R1) and CRF 2a receptor (CRF-R2a) in the brain does not coincide completely with either CRF or CRF-BP mRNA.

Peripheral Corticotropin Releasing Factor-Binding Protein

It is suspected that, in addition to the brain form, only higher primates have circulating CRF-BP. Humans express CRF-BP in the liver, and it circulates in the plasma of both sexes at concentrations, measured by immunoradiometric assay, of between 50 and 100 $\mu\text{g liter}^{-1}$. The liver is the probable source of CRF-BP in plasma because concentrations are much reduced in patients with chronic liver disease. By contrast, kidney failure is associated with elevated plasma levels, indicating that CRF-BP (not bound to ligand) is normally cleared by the renal route. Plasma levels are remarkably constant from day to day. In molar terms, plasma CRF-BP vastly exceeds CRF and therefore never approaches saturation by ligand except in the last few weeks of pregnancy. The placenta of primates also expresses CRF, and it has been suggested that the binding protein serves in late pregnancy to help prevent the stimulation of the maternal pituitary by releasing large amounts of placental CRF into the circulation. Not only is hormonal activity abolished after binding to CRF-BP, but it is in the bound form that most CRF may be removed from the maternal circulation. The CRF-BP is also measurable in fetal blood and amniotic fluid and may have a further role in the modulation of CRF activity associated with the onset of labor. CRF stimulates the release of prostaglandins from

fetal membranes and potentiates their induction of myometrial contractility. These activities are presumed to be modulated by CRF-BP in the fetal and maternal circulation.

In contrast to late pregnancy, when the plasma levels of CRF-BP are lower than normal, in both rheumatoid arthritis and septicemia the concentrations are significantly elevated (by up to 50%). Whereas the lowering of CRF-BP levels in pregnancy seems to be triggered by the secretion of placental CRF, the raised levels in these active immune states appear to be caused by increased secretion by the liver. Presumably this is due to the activation of the acute-phase response elements found in the 5' flanking region of the CRF-BP gene. It is likely that the bioactivity of circulating CRF is always attended by some degree of modification imposed by the presence of its binding protein.

Properties

Ligand Binding

The affinity of human CRF-BP for human CRF is high ($K_d = 0.1$ nM). That for ovine CRF, which differs at 7 of the 41 amino acid residues, is 200-fold lower; however, CRFs from both species have equal affinities for the pituitary CRF-R1. Sheep CRF-BP has an 86% homology in its amino acid sequence with human and rat CRF-BP, yet it binds human CRF with a 10-fold higher affinity than ovine (CRF $K_d = 0.15$ nM, as opposed to 1.75 nM). Furthermore, a truncated version of human CRF, CRF (6–33), binds CRF-BP with reduced affinity but does not bind to CRF-R1, CRF-R2a, or CRF-R2b. These considerations indicate that the structural determinants required for ligand binding by the

Table 1 Order of ligand affinities for CRF-BP and the CRF receptors

CRF-BP	Urotensin > urocortin ≥ hCRF > sauvagine > oCRF
CRF-R1	Urocortin > hCRF = oCRF = urotensin = sauvagine
CRF-R2a	Urocortin > sauvagine > urotensin > hCRF > oCRF
CRF-R2b	Urocortin > sauvagine = urotensin > hCRF = oCRF

binding proteins and CRF-R1 are very different. The recent discovery of urocortin, a new member of the CRF family of peptides, has shown that CRF receptor-binding protein interactions may be further complicated by the participations of additional ligands. Discrepancies in the central distribution of the CRF receptors, CRF-BP, and CRF terminals is evidence that novel ligands for CRF-BP remain to be discovered. The relative affinities for CRF and CRF-like ligands are shown in Table 1.

With the exception of the synthetic peptide antagonist α -helical CRF(9–41), CRF-like ligands interacting with CRF-BP *in vitro* induce dimerization. The formation of dimers has not been demonstrated to occur *in vivo*, but CRF administered to humans intravenously is cleared rapidly from the circulation. The possibility therefore exists that CRF-BP not only inactivates CRF but, by dimerizing, targets the ligand for elimination.

Physicochemical Properties

CRF-BP has a molecular mass of 37 kDa, and the mature polypeptide consists of 298 amino acid residues. Its structure is composed predominantly of a β -sheet with little evidence of α -helical folding.

CRF-BP is subject to two posttranslational modifications. These have been investigated using human

recombinant CRF-BP. It has a consensus sequence for N-glycosylation of asparagine residue 204. Enzymic removal of the glycosyl moiety does not affect the binding of CRF. A potential phosphorylation site exists at serine residue 233, although phosphorylation has been found by experiment to occur instead at serine 206. On storage, affinity-purified recombinant CRF-BP also undergoes cleavage between amino acid residues 234 and 235, even in the presence of protease inhibitors, yielding fragments of 28 and 9.6 kDa molecular mass. Some degree of protein unfolding has been observed, by tryptophan excitation fluorescence, to occur prior to this *in vitro* cleavage. It is not known whether it is accompanied by dephosphorylation. Protein fragments of similar size have been observed in the synovial fluid of patients suffering from rheumatoid arthritis, although it is not clear whether this is a consequence of the inflammation or if it is involved in the pathogenesis of this condition. Under nonpathological conditions, insulinlike growth factor (IGF)-binding proteins also undergo dephosphorylation and cleavage, both of which are regulated by and affect ligand binding. In the case of IGF-binding protein-3, cleavage is regulated by IGF-1. The cleavage of IGF-binding proteins reduces their affinity for ligand, whereas, after cleavage of CRF-BP, the binding of human CRF to the 28-kDa N-terminal fragment is unimpaired.

Regulation of Gene Expression

The characterization of the upstream region of the CRF-BP gene has revealed acute-phase response elements, one of which (located at -305) is known to bind the transcription factor nuclear factor (NF)- κ B. This factor, which regulates immunoglobulin and interleukin expression, is thought to be important in activating liver-specific genes, such as angiotensin, in response to acute stress, inflammation, and injury. Another element (located at -676) binds interferon (INF)-1, which is known to regulate the interferon gene.

More recent evidence has revealed multiple potential transcription-factor binding sites in the 5' flanking region of both the rat and human CRF-BP gene. These include a cAMP response element binding protein (CREB)/activating transcription factor (ATF) site, a liver factor (LF)-A1 site, an oxytocin (OTX) site, an activating enhancer binding protein (AP)-2 site, two stimulating protein (Sp)1 sites, and two AP-1 sites, as well as those mentioned previously. The CREB/ATF and AP-2 sites suggest that cAMP may be important for the regulation of the CRF-BP gene, and this is corroborated by the fact that primary rat neuronal or astrocyte cultures, stimulated with forskolin

or isobutylmethylxanthine, have been shown to increase levels of CRF-BP mRNA. It has also been demonstrated using the G_s-protein-coupled CRF receptor in the AtT-20 pituitary cell line that CRF-BP gene expression is positively regulated by CRF, suggesting a mechanism for refining the action of CRF on the stress axis at the level of gene expression.

Role of Corticotropin Releasing Hormone-Binding Protein in the Stress Response

The stress axis and the immune system are interrelated, and stress influences the course and pathology of the immune response to infectious disease and to autoimmune stimuli. Intravenous administration of CRF, a key component of the stress axis, elicits visceral and neuroendocrine changes that mimic the body's reaction to stress. Peripheral CRF receptors have been identified on cells of the testes, ovaries, adrenal medulla, heart, uterus, skeletal muscle, lung, kidney, and vasculature. Furthermore, CRF receptors have been reported to exist on circulating lymphocytes and macrophages as well as on mast cells. There is evidence for the hypothesis that peripheral proinflammatory effects of CRF in humans may be modulated by circulating CRF-BP, whereas the central anti-inflammatory response to stress may be modulated by membrane-bound CRF-BP in the brain. It has been shown that CRF is displaced from CRF-BP when human brain tissue is treated with an analog of CRF that displaces bound CRF. *In vivo*, the displacement of CRF from CRF-BP by the central administration of a truncated form of CRF (CRF(6-33)) to rats had an anxiolytic effect. It improved learning and memory presumably by making more free CRF available to interact with CRF receptors. These observations demonstrate that CRF-BP is certainly capable of modulating the actions of CRF.

Glucocorticoids in Affective Disorders: Early Evidence

Evidence linking the hypothalamic-pituitary-adrenal (HPA) axis abnormalities with psychiatric symptoms dates back over 100 years. The occurrence of depression, anxiety, and in extreme cases psychosis, in both Cushing and Addison diseases, which are associated with excessive or markedly reduced levels of circulating glucocorticoids, respectively, served as an initial impetus for researchers to scrutinize HPA-axis function in psychiatric disorders. Some of the first direct evidence that posited a role between glucocorticoids

and mood stemmed from studies that were carried out in the 1950s.

The concatenation of several lines of evidence revealed abnormalities in glucocorticoid (i.e., cortisol) function in depressed patients. These include elevated plasma cortisol concentrations, increased 24-h urinary free cortisol concentrations, and increased levels of cortisol metabolites in urine. Although not observed in every patient with major depression, elevated cortisol secretion in depression is among the most reproducible findings in all of biologic psychiatry.

Structural changes in the components of the HPA axis have also been documented in depressed patients. These include pituitary gland enlargement as demonstrated by magnetic resonance imaging (MRI) and moreover, the adrenal glands have also shown to be enlarged in depression as assessed by both imaging studies, as well as postmortem analysis of the adrenals, presumably due to the effects of adrenocorticotrophic hormone (ACTH) hypersecretion.

Corticotropin-Releasing Factor

Although Saffran and Schally identified a crude extract that promoted the release of ACTH from the pituitary in 1955, the ultimate regulator of ACTH and cortisol release, corticotropin-releasing factor (CRF), was not isolated and chemically characterized until 1981. Working with extracts derived from 500 000 sheep hypothalami, Vale and colleagues at the Salk Institute elucidated the structure of CRF. This

discovery led to the availability of synthetic CRF, which allowed for a comprehensive assessment of the HPA axis. Based on findings from numerous studies it is clear that CRF coordinates the endocrine, immune, autonomic, and behavioral responses of mammals to stress.

The hypothalamus serves as a regulatory point for a number of key functions including body temperature, hunger, thirst, and circadian cycles. Within the hypothalamus, CRF is synthesized primarily in the parvocellular neurons of the paraventricular nucleus (PVN). These PVN CRF neurons receive input from a variety of brain regions, including the amygdala, the bed nucleus of the stria terminalis (BNST), and the brain stem. CRF-containing neurons within the hypothalamus then project to the median eminence. The median eminence serves as a bridge between the hypothalamus and the anterior lobe of the pituitary gland. Within the median eminence, the release and release-inhibiting hypothalamic hypophysiotropic hormones are released from nerve terminals and enter the portal blood system which supplies the anterior pituitary gland.

In response to a variety of stressors, this neural circuit becomes activated, thereby releasing CRF into the hypothalamo-hypophysial portal system, where it activates CRF receptors on corticotrophs in the adenohypophysis to promote the synthesis of pro-opiomelanocortin and the release of its major posttranslation products, ACTH and β -endorphin. ACTH, released from the anterior pituitary, stimulates the production and release of cortisol from the adrenal cortex. These same hypothalamic CRF neurons also project to the spinal cord and brainstem nuclei, including the locus coeruleus (LC), the site of the noradrenergic neurons that project to the forebrain. Magnocellular neurons (literally large cells) in the PVN also produce vasopressin and oxytocin. Vasopressin has been regarded to potentiate the action of CRF on ACTH secretion.

Corticotropin-Releasing Factor Receptors

Two CRF receptor subtypes, CRF₁ and CRF₂, with distinct anatomic localization and receptor pharmacology, have been identified in rats and humans. Both receptors are members of the large G-protein receptor superfamily. The CRF₁ receptor is predominantly expressed in the pituitary, cerebellum, and neocortex in rats. Considerable evidence from laboratory animal studies has shown that CRF₁ receptors may specifically mediate some of the anxiogenic-like behaviors observed after administration of CRF.

In agreement with these findings, mice that have had their CRF₁ receptor knocked out were found to exhibit an impaired stress response. The CRF₁ receptor knockout mice were less anxious than their wild-type litter mates when tested in the elevated plus maze, a commonly used animal model of anxiety. This paradigm consists of an elevated maze in which two of the arms contain walls, whereas the other two arms are open. Rodents that spend more time on the open arms, where they are potentially exposed to predators or more likely could fall, are generally interpreted to be less anxious than animals that spend the preponderance of time in the closed arms. In addition, data in these transgenic mice showed a significant reduction in stress-induced release of ACTH and corticosterone (the primary glucocorticoid in rodents).

CRF₂ receptor knockout mice have also been generated. Deletion of the CRF₂ receptor gene during development has provided conflicting results, with increased anxiety observed in some but not all paradigms tested. These studies suggest that CRF₂ receptor blockade may lead to states of increased anxiety, though it is likely that both the environment and the genetic background on which the knockouts were bred contribute to the behavioral phenotype of these animals.

Research using selective CRF₂ receptor agonists and antagonists have also provided inconsistent results. Several studies have used the selective CRF₂ receptor antagonist antisauvagine-30 (ASV-30), which has been reported to be between 100- and 1000-fold selective for the CRF₂ receptor, depending upon whether the radiolabeled ligand is sauvagine or ASV-30, respectively. Direct administration of ASV-30 into the lateral septum was shown to reduce anxious behavior induced by immobilization stress in the elevated plus maze paradigm or by previous association with foot shock in mice. These behavioral data were corroborated in rats, where direct injection of ASV-30 into the cerebral ventricles reduced anxious behavior in the plus maze, defensive withdrawal, and a conditioned anxiety paradigm.

Compounds which selectively activate (i.e., agonists) the CRF₂ receptor have also been discovered. The peptides urocortin 2 and urocortin 3 are structurally and ancestrally related to CRF but show between 100- and 1000-fold selectivity at the CRF₂ receptor versus the CRF₁ receptor. Urocortin 3 has been shown to mildly suppress locomotion and has an anxiolytic-like profile in mice. However, another study from the same group of researchers demonstrated that urocortin 2 was inactive in the plus maze after acute administration but did increase exploratory behavior in the plus maze 4 h later.

Thus, compounds reported to be both selective agonists and antagonists at the CRF₂ receptor have been shown to possess anxiolytic effects; clearly the precise role of this receptor in modulating stress-induced behaviors remains obscure.

Extrahypothalamic Corticotropin-Releasing Factor Circuits and Depression

Although initially investigated for its role as one of the key modulators of the HPA axis, further research has revealed that CRF controls not only the neuroendocrine, but also the autonomic (e.g., heart rate, blood pressure, etc.), immune, and behavioral responses to stress in mammals. Results from both clinical studies and a rich body of literature conducted primarily in rodents and nonhuman primates have highlighted the importance of extrahypothalamic CRF neurons. In rodents, primates, and humans, CRF and its receptors are heterogeneously localized with high concentrations in a variety of regions, including the amygdala, thalamus, hippocampus, and prefrontal cortex, among others. These brain regions serve as key regulators of the mammalian stress response and emotion.

The presence of CRF receptors in both the dorsal raphe and LC, the origin of the major serotonergic- and noradrenergic-containing perikarya, respectively, also deserves comment because most available antidepressants, including the tricyclic antidepressants and selective serotonin-releasing inhibitors (SSRIs), are believed to act via modulation of the serotonergic and/or noradrenergic systems. The neuroanatomic proximity of CRF and monoaminergic systems provides evidence for an interaction between CRF systems and certain antidepressants, thereby suggesting a mechanism by which antidepressants may affect the CRF system.

Corticotropin-Releasing Factor in Depression

Among the affective disorders, the role of CRF in major depression has been the most thoroughly investigated. Shortly after the isolation and characterization of CRF, a standardized intravenous CRF stimulation test was developed to assess HPA-axis activity. In this paradigm, CRF is administered intravenously (usually at a dose of 1 µg kg⁻¹ or a fixed dose of 100 µg), and the ACTH and cortisol responses are measured at 30-min intervals over a 2–3-h period. Numerous studies have now documented a blunted ACTH and β-endorphin response to intravenously administered ovine or human CRF in depressed patients compared with nondepressed people; the cortisol response in depressed patients and nondepressed

control subjects did not consistently differ. This was one piece of evidence that contributed to the initial hypothesis that CRF may be hypersecreted in a subset of depressed patients.

More specifically, the attenuated ACTH response to CRF has been hypothesized to be due to chronic hypersecretion of CRF from nerve terminals in the median eminence, which results in downregulation of CRF receptors in the anterior pituitary, and/or to chronic hypercortisolemia and its associated negative feedback. CRF receptor downregulation results in reduced responsivity of the anterior pituitary to CRF, as has been repeatedly demonstrated in laboratory animals.

In support of the involvement of extrahypothalamic CRF systems in the pathophysiology of depression, numerous studies have demonstrated elevated CRF concentrations in the cerebrospinal fluid (CSF) of depressed patients, though some discrepant results have also been reported. It is likely that this increased CSF CRF is due to hypersecretion not only from hypothalamic CRF nerve terminals, but from extrahypothalamic sites as well.

Elevated CSF CRF concentrations have also been detected in depressed suicide victims. A reduction in concentrations of CRF in CSF has been reported in healthy volunteers treated with the tricyclic antidepressant desipramine and in depressed patients following treatment with fluoxetine or amitriptyline, providing further evidence of an interconnection between antidepressants, monoamine neurons, and CRF systems. Similar effects have also been reported after electroconvulsive therapy (ECT) in depressed patients.

The alterations in CSF CRF concentrations appear to represent a state, rather than a trait, marker of depression (i.e., a marker of current depression rather than a marker of vulnerability to depression). Furthermore, high and/or increasing CSF CRF concentrations despite symptomatic improvement of major depression during antidepressant treatment may be the harbinger of early relapse.

Consistent with altered concentrations of CRF found in clinical studies of depression, CRF binding site density and messenger ribonucleic acid (mRNA) expression have shown alterations in both preclinical and clinical studies, presumably in response to changes in CRF availability. Our group has previously reported a marked (23%) reduction in the number of CRF binding sites in the frontal cortex of suicide victims compared with controls; we have now replicated this finding in a second study. Raadsheer and colleagues demonstrated an increase in CRF mRNA expression in the PVN of depressed patients compared with controls.

Increased CRF mRNA and decreased CRF₁ mRNA have also been detected in the brains of suicide victims in subregions of the frontal cortex. Although conducted in different laboratories and on different tissue, and keeping in mind the relative difficulty in obtaining and analyzing human tissue, the general pattern of increased CRF concentrations and/or CRF mRNA and the relative decrease in CRF binding sites is consistent with the well-documented phenomenon of receptor up- and downregulation and the CRF hypersecretion hypothesis of depression.

While the exact mechanism contributing to CRF hyperactivity remains obscure, studies from our group and others have documented long-term persistent increases in HPA-axis activity and extrahypothalamic CRF neuronal activity after exposure to early untoward life events, e.g., neglect and child abuse, respectively, in both laboratory animals (rats and nonhuman primates), and patients. Early life stress apparently permanently sensitizes the HPA axis and extrahypothalamic CRF neurons and leads to a greater risk of depression developing later in life.

To measure HPA-axis responsivity to stress in humans, the Trier Social Stress Test (TSST) was developed. This laboratory paradigm involves a simulated 10-min public speech followed by a difficult mental arithmetic task. The TSST has been validated as a potent activator of the HPA axis in humans. Our group reported increased HPA-axis responsivity, presumably due to hypersecretion of CRF, after exposure to the TSST in both depressed and nondepressed women who were exposed to severe physical and emotional trauma as children. These data strongly suggest that CRF systems are particularly sensitive to the effects of early adverse life events.

Corticotropin-Releasing Factor and Anxiety Disorders

Involvement of CRF in anxiety disorders has been well documented in both animal and human studies. Best studied among this diverse group of disorders is posttraumatic stress disorder (PTSD), which has been most commonly studied in Vietnam combat veterans, though it is now widely recognized to occur after other life-threatening situations including victims of rape, natural disasters, and physical and sexual abuse as children. Combat veterans with PTSD exhibit significantly elevated CSF CRF concentrations, as well as alterations in the ACTH response to CRF challenge. In contrast to studies from depressed patients, low serum cortisol and urinary free cortisol levels have been repeatedly, yet unexpectedly, detected in PTSD, especially after dexamethasone administration. One

possible mechanism that has been proposed by Yehuda and colleagues to explain these findings is heightened negative glucocorticoid feedback within the HPA axis in chronic PTSD patients.

Elevated CSF CRF concentrations have not been detected in patients with panic disorder, though a blunted ACTH response after CRF administration has been observed. Increased or normal concentrations of CSF CRF have been observed in patients with obsessive-compulsive disorder (OCD), though significant decreases in CSF CRF concentrations have been noted following a therapeutic response to clomipramine. Patients with generalized anxiety disorder (GAD), however, exhibit similar CSF CRF concentrations in comparison to normal controls.

Not surprisingly, increased concentrations of CSF CRF occur in alcohol withdrawal, a condition of sympathetic nervous system arousal and increased anxiety. In contrast, CSF CRF concentrations are reduced or are normal in abstinent chronic alcoholics with normal plasma cortisol concentrations. Although human data are limited in other addictive states, there is also a burgeoning laboratory animal literature which suggests that CRF may play a role in both the withdrawal and/or stress-induced drug relapse of a number of addictive compounds including nicotine, alcohol, cocaine, and benzodiazepines. To understand the exact role of CRF in anxiety will require considerable additional study.

Small-Molecule Corticotropin-Releasing Factor Antagonists

Although space constraints do not permit an extensive review of the entire preclinical literature, several additional points are worth noting. Findings from numerous studies have shown that when CRF is directly injected into the central nervous system (CNS) of laboratory animals it produces effects reminiscent of the cardinal symptoms of depression, including decreased libido, reduced appetite and weight loss, sleep disturbances, and neophobia. Certainly, by the late 1980s, a number of research groups, including our own, had hypothesized that a lipophilic, small-molecule CRF receptor antagonist that readily penetrates the blood-brain barrier after oral administration would represent a novel class of antidepressant and/or anxiolytic agents.

CRF₁ receptor antagonists possess activity in both animal models of anxiety and depression. CRF receptor antagonists have been tested in many different paradigms, including the elevated plus maze, foot shock, restraint stress, and defensive withdrawal. Pretreatment with CRF receptor antagonists decreases

measures of anxiety induced by stressors. There is also some evidence that CRF receptor antagonists may reduce the effects of drug withdrawal and stress-induced relapse to drug seeking in rats. Based on this premise, newly developed CRF₁ receptor antagonists represent a novel putative class of antidepressants. Such compounds show activity in nearly every preclinical screening test for antidepressant and anxiolytic drugs.

Despite the rich preclinical and clinical literature supporting a potential role for CRF₁ receptor antagonists, there has only been one published study investigating the effects of a CRF₁ receptor antagonist in humans. A small open-label study examining the effectiveness of R121919, a CRF₁ receptor antagonist, in major depression was completed more than 5 years ago. This study of 20 patients showed that R121919 (5–40 mg day⁻¹ or 40–80 mg day⁻¹ for 30 days) was well tolerated and did not significantly affect plasma ACTH or cortisol concentrations at baseline or following CRF challenge. It is important that any potential CRF antagonist not lead to adrenal insufficiency, which can, of course, have grave medical consequences. Hamilton Depression Rating Scale and Hamilton Anxiety Scale severity scores were both significantly reduced following 30-day treatment with this drug. Although this small, pilot study does not provide unequivocal proof, it does provide further evidence that a selective CRF-receptor antagonist may possess antidepressant and antianxiety properties in humans. Although this drug is no longer in clinical development because of hepatotoxicity, several novel CRF₁ antagonists are currently under investigation.

Conclusions and Future Directions

Since the discovery of CRF more than 25 years ago, evidence has accumulated that it plays a preeminent role in the physiology of the stress response. Moreover the evidence of its involvement in pathophysiologic states such as major depression and anxiety disorders is compelling. The recent introduction of small-molecule CRF receptor antagonists as a putative novel class of antidepressant and anxiolytic drugs remains very promising. These compounds block the

actions of exogenous and endogenous CRF in a variety of *in vivo* models, supporting a putative role for these agents in the treatment of stress and/or anxiety and affective disorders. The promising clinical results in patients with depression in the completed open trial of R121919 is of great interest and the results of controlled studies are eagerly awaited.

Glossary

<i>Corticotropin releasing factor (CRF)</i>	A hypothalamic neuropeptide produced in response to stress; it regulates the production of cortisol from the adrenal glands via the hypothalamic-pituitary-adrenal axis. CRF is also produced in the brain and peripheral tissues, including the immune cells.
<i>Inflammation</i>	The first line of immune defense against a broad spectrum of molecules; the clinical sign characteristics are swelling, redness, fever, and pain. It can be acute or chronic, local or generalized. Exposure to chemicals, microorganisms or physical damage initiates the inflammatory response characterized by a cellular and noncellular (exudative) component.
<i>Urocortins</i>	Neuropeptides with high homology/chemical resemblance to CRF. They are produced in the brain and peripheral tissues, including the immune cells. There are three urocortin molecules: urocortin 1, urocortin 2 (or stresscopin-related peptide), and urocortin 3 (or stresscopin).

The Corticotropin Releasing Factor Family of Neuropeptides and Their Receptors

Corticotropin Releasing Factor

CRF, a 41-amino-acid hypothalamic peptide, is the primary hypothalamic hormone involved in the mammalian response to stress. Stress is defined as any threat to homeostasis. CRF coordinates the homeostatic

mechanisms necessary for an organism to cope with internal or external threats. The stress-regulating CRF is produced in the parvocellular neurons of the paraventricular hypothalamic nucleus, which receive innervation from higher central nervous system (CNS) areas and from the periphery. CRF is released into the hypophyseal portal circulation and travels to anterior pituitary lobe, where it binds to specific CRF sites, the CRF receptors type 1, stimulating the production of proopiomelanocortin (POMC) by corticotroph cells. POMC is then cleaved into adrenocorticotrophic hormone (ACTH), a systemic hormone that stimulates cortisol production from the adrenal gland; cortisol is the principal stress hormone in humans. At the same time, several parvocellular CRF neurons project into locus coeruleus, the command center of sympathetic system, the second major adaptation mechanism to stress. CRF enhances central sympathetic outflow. In addition to its synthesis in the hypothalamus, CRF is also produced throughout the brain, where it works as a peptide neurotransmitter. In general, in the brain CRF stimulates the stress axes and mediates anxiogenic effects. CRF is also present in peripheral tissues including the heart, gastrointestinal (GI) tract, skin, gonads, adrenals, and several components of the immune system including the lymphocytes, splenocytes, neutrophils, mast cells, and monocytes/macrophages.

The Urocortins

There are three urocortin molecules. Urocortin 1 is a 40-amino-acid peptide first isolated from rat brain by molecular cloning in 1995. It exhibits 45% homology with CRF and 63% homology with urotensin, a neuropeptide found in teleost fish. Urocortin 1 strongly binds and stimulates the CRF1 and CRF2 receptors. Like CRF, it can stimulate ACTH secretion from anterior pituitary corticotrophs *in vitro* and *in vivo*. Urocortin 1 is more potent than CRF in decreasing feeding in both meal-deprived and free-feeding rats. Urocortin 1 suppresses feeding via CRF2 receptors.

Urocortin 2, also known as stresscopin-related peptide, and urocortin 3 (stresscopin) are 38-amino-acid peptides and share high homology. They are selective ligands for the CRF2 receptor and thus they share several common effects with urocortin 1 in

appetite suppression, delay of gastric emptying, and cardiovascular effects. They are expressed in several areas of the brain, including the hypothalamus, amygdala, and brain stem, and in the periphery in the GI tract, skin, adrenals, and cardiovascular system.

The Corticotropin Releasing Factor Receptors

The biological effects of CRF peptides are mediated by CRF receptor type 1 (CRF1) and CRF2. CRF2 exists in at least three isoforms, resulting from alternative splicing, the CRF α , CRF β , and CRF γ . The CRF receptors belong to the class B subdivision of G-protein-coupled membrane receptor superfamily. CRF1 and the CRF2 α and CRF2 γ receptors are expressed throughout the brain, whereas CRF2 β is mainly expressed in the periphery, in the lung, skeletal muscles, gonads, cardiac myocytes, skin, GI tract, adrenals, and many immune cells. In the CNS, the CRF2 receptors mediate a central anxiolytic response, opposing the general anxiogenic effect of CRF, which is mediated by the CRF1 receptor. Mice overexpressing CRF show anxiogenic-like responses compared to wild-type mice, whereas mice lacking the CRF1 receptor show an anxiolytic-like behavior. It thus appears that the activation of the CRF1 receptors prepare the organism to respond to stress at a somatic level (activation of the hypothalamus-pituitary-adrenal axis and the sympathetic nervous system) and behaviorally (i.e., the anxiogenic-like response). CRF2 receptors adapt the organism to stress and ameliorate the stress response. Finally, a third type of receptor, the CRF-binding protein (CRFBP), is a pseudoreceptor whose primary function is to compete with CRF receptors for the CRF ligands, thus making it unavailable to the bioactive CRF receptors. CRFBP is mainly expressed in the CNS and peripheral nervous system.

The Inflammatory Response

A Brief Description of Inflammation

Inflammation is the first line of immune defense against a broad spectrum of molecules. This biologically ancient and nonspecific process is part of the innate immunity system. It does not possess a mechanism for memorizing the offending event and, thus, does not confer a lasting immunity against it. If innate immunity is overwhelmed, then a biologically more recent immune mechanism takes control – acquired immunity, a complex process that memorizes the event and confers lasting and specific immunity.

Basic Concepts in the Physiology of the Inflammatory Response

Inflammation can be acute or chronic, local or generalized. Exposure to chemicals, microorganisms or physical damage initiates the inflammatory response characterized by a cellular and a noncellular (exudative) component. The first cells to gather at an inflammation site are the neutrophils (polymorphonuclear cells). Neutrophils live for 1–2 days, and they are gradually replaced by monocytes, which mature to macrophages. All these cells cross the vascular wall and enter the inflammation site. There, they secrete pro- and anti-inflammatory substances, including cytokines, chemokines, and adhesion molecules; clean the area from microbes and cellular debris by phagocytosis; chemoattract other immune cells; and finally act as antigen-presenting cells. The pro-inflammatory cytokines interleukin (IL-)1 and IL-6 and tumor necrosis factor (TNF-) α activate endothelial cells to produce specific membrane receptors (vascular adhesion molecule 1, VCAM-1; intercellular adhesion molecule 1, ICAM-1; selectins), which bind immune cells. The exudative component consists of fluid moving from the intravascular space, due to the increased permeability of the vascular wall. It consists of fibrins and several types of immunoglobulins. These phenomena at an inflammation site produce the clinical characteristics of inflammation: swelling, redness, fever, and pain (tumor, rubor, calor, and dolor, in Latin). If the inflammatory response is large, it can cause systemic symptoms including fever, chills, fatigue, loss of appetite, and mental confusion. If the acute inflammatory response cannot isolate and destroy the offending agent, T lymphocytes take over, shifting the response to chronic inflammation by recruiting B lymphocytes, macrophages, and fibroblasts. Note that arteriosclerosis is now considered the most significant (in terms of threat to health) consequence of a chronic low-level inflammatory response.

Corticotropin Releasing Factor, Urocortins, and Inflammation

CRF regulates the production of cortisol via the hypothalamic-pituitary-adrenal axis. Cortisol, like all glucocorticoids, affects the immune system at multiple levels. Most of its effects are suppressive. Indeed, glucocorticoids are used extensively in suppressing the immune system in autoimmune diseases. During the last 20 years, it became gradually apparent that CRF and the urocortins affect the immune system independently of cortisol in a direct and paracrine

manner via the CRF receptors present, as previously stated, in most immune cells. CRF and the urocortins reach the immune cells and the sites of inflammation either via axonal transport through the autonomic nerves or by being produced ad hoc by the epithelial, the endothelial, and the immune cells themselves. Indeed, it has been shown that human mast cells, lymphocytes, monocytes/macrophages, murine neutrophils, and splenic T lymphocytes produce the CRF family of peptides as well as their receptors. In addition, it is now known that the levels of these peptides and their receptors increase at inflammation sites at a level parallel to the degree of the inflammatory response. In particular, high levels of CRF and urocortins have been found in experimentally induced inflammation, for example, in the inflamed synovia of patients with rheumatoid arthritis, in the inflamed colonic mucosa of patients with ulcerative colitis, and in the inflamed uvea. The concentration of CRF peptides also increases in human endometrium at the sites of egg nidation and implantation, both well-described inflammatory phenomena.

Corticotropin Releasing Factor Peptides and Immune Cells

Mast Cells

It appears that mast cells represent one of the principal immune cell targets of CRF peptides. Indeed, the exposure of mast cells to CRF results in their immediate degranulation of pro-inflammatory mediators, an effect blocked by CRF1 antagonists (molecules that bind to the CRF1 receptor, inhibiting its function). Human mast cells synthesize CRF, urocortins, and CRF1 and CRF2 receptors. The activation of immunoglobulin E receptor induces the synthesis and secretion of both CRF and urocortins. It has recently been suggested that in the skin, mast cells, neurons, and keratinocytes interact via several substances including the CRF peptides. This cutaneous cellular network may be involved in the exacerbation of atopic dermatitis, psoriasis, and other skin ailments following stressful situations (neurogenic inflammation).

Macrophages

Macrophages are among the initiator cells during the inflammatory response and represent the main source of pro-inflammatory cytokines. The activation of macrophages occurs through antigenic signals, including bacterial lipopolysaccharide (LPS), which binds to toll-like receptor (TLR)-4; the activation

of the latter results in an induction of cytokine production and secretion. CRF augments LPS-induced pro-inflammatory cytokine production from macrophages. This effect of the CRF family of peptides appears to be due to their effect on the expression of TLR-4 receptors on macrophages. This effect occurs at the transcriptional level. Indeed, CRF peptides activate TLR-4 in macrophages transfected with a construct containing the proximal region of the TLR-4 promoter linked to luciferase gene. This effect is abolished on mutation of the proximal to the initiation codon PU.1 binding site or on mutation of the activating enhancer binding protein (AP-1) binding element. In addition, CRF peptides block the well-known inhibitory effect of LPS on TLR-4 expression.

Corticotropin Releasing Factor Peptides Modulate Inflammation at a Local Paracrine Level

Multiple published reports suggest that CRF and the urocortins modulate the inflammatory response at a local, ad hoc level. Indeed, several published reports have shown that the CRF peptides affect the inflammatory response at several steps, including neutrophil and macrophage recruitment and migration, phagocytosis, production of cytokines and chemokines, production of adhesion molecules, capillary permeability, angiogenesis, and antigen presentation. Furthermore, the blockade of CRF receptors in several experimental models of inflammation or in stress-induced colitis suppresses immune cell migration, exudate production, the levels of cytokines, ionic and macromolecular permeability of vascular wall, and several other phenomena associated with inflammation.

Corticotropin Releasing Factor Peptides in the Gastrointestinal Tract

As previously stated, CRF, the urocortins, and their receptors are expressed throughout the GI tract. CRF is mainly produced by the normal enterochromaffin cells in the lower GI tract, whereas the urocortins are produced mostly in the upper GI tract by epithelial cells. The activation of the CRF1 receptor stimulates colonic motility, whereas the activation of the CRF2 receptor inhibits gastric emptying.

Gastrointestinal inflammation As previously stated, CRF and urocortins play a major role in the inflammatory phenomena taking place in the GI tract. In patients with ulcerative colitis, CRF intensifies mucosal inflammation in a paracrine manner. Thus, in the lower GI tract, CRF appears to be a major

pro-inflammatory agent. In the stomach, the story appears to be a little different. Urocortin appears to be the major player in the stomach, where it acts as an anti-inflammatory agent. We have studied the role of stomach urocortin in humans with *Helicobacter pylori* (HP) gastritis. The concentration of urocortin is higher in gastric biopsies from patients with active HP gastritis than in normal controls. Following the apparent eradication of HP infection, by clinical and microscopic criteria, urocortin levels increase dramatically compared to pretreatment values. The nonresponders to HP eradication treatment do not appear to be able to elevate their levels of urocortin 1 in their gastric epithelium. In summary, it appears that CRF plays a pro-inflammatory role in inflammatory diseases of the bowel, whereas urocortins play an anti-inflammatory role in the stomach. These differences between upper and lower GI tracts may explain in part the lack of severe chronic inflammatory diseases in the stomach compared to the prevalence of chronic inflammatory bowel syndromes.

Corticotropin Releasing Factor Peptides and Endometrial Decidualization

CRF, the urocortins, and their receptors are expressed in the human endometrium, the maternal reception area for the fertilized egg. During the early stages of egg apposition, endometrial stroma is differentiated into decidua, a thick and sticky area that attracts and traps the fertilized egg. The decidualization of endometrial stroma has characteristics of a local aseptic inflammatory reaction, playing a crucial role in the implantation of the fertilized egg and the continuation of pregnancy. It now appears that the CRF peptides play a major role in the decidualization of endometrial stroma. Indeed, they potentiate the decidualizing effect of progesterone, the principal gonadal steroid hormone of pregnancy. Interestingly, progesterone appears to induce the expression of endometrial CRF, thus forming a local self-augmenting loop with the CRF peptides. In addition to progesterone, several other locally produced pro-inflammatory immune factors modulate decidualization, including prostaglandins and interleukins. Endometrial CRF peptides and the interleukins interact with progesterone to fine-tune and control the phenomenon of decidualization. The sequence of events appears to be as follows. Progesterone, in addition to its strong direct decidualizing effect, induces the production of endometrial CRF peptides, which potentiate the effect of progesterone on stromal decidualization. They also affect local immune modulators inhibiting, among others, the enhancing effect of prostaglandin E2 (PGE2), inducing the inhibitory effect of IL-1 and

stimulating the inducing effect of IL-6. This complex interaction results in the optimal decidualization of human endometrium, making it ready to receive the fertilized egg.

Endometrial implantation of the fertilized egg Apart from the endometrium, the implanting blastocyst (i.e., the fertilized egg composed of approximately 16–32 cells) also secretes several pro-inflammatory mediators, including IL-1 and PGE2. Blastocyst-deriving IL-1 plays an essential role in the implantation process, inducing the production of endometrial CRF peptides at the very site of implantation, rendering thus the local endometrial surface extremely adhesive for its attachment. This process leads to the formation of the egg nidus. The pivotal role of the CRF peptides on egg implantation is supported by several lines of evidence showing a significantly higher concentration of CRF peptides at the early implantation site compared to the interimplantation uterine areas. In addition, IL-1 receptor antagonists block egg implantation and early pregnancy in mice. *In vivo* experiments in mice have shown that intraperitoneal injections of CRF antibodies at day 2 of pregnancy decrease the number of fetuses by at least 60%. These data are further supported by experiments in rats using CRF1 receptor antagonists, which cause a dramatic reduction of the number of implantation sites. Thus, blocking of CRF has an antinidation effect at an early stage of pregnancy. Recent experimental findings support this hypothesis. It should be noted that the implanting egg should be viewed as a semi-xenograft containing paternal antigens, which may activate the maternal immune system, leading to embryo resorption. CRF, by stimulating the expression of the pro-apoptotic FasL protein in the decidual and trophoblastic cells, induces apoptosis (a genetically programmed form of cell death) of the surrounding maternal T lymphocytes, thus rescuing the implanted egg from the maternal immune defense. Expression of Fas ligand by fetal extravillous trophoblast cells induces apoptosis of activated T lymphocytes expressing the Fas receptor on their membranes. Inadequate CRF-mediated self-induction of FasL in extravillous trophoblasts may cause recurrent spontaneous abortions. Indeed, bridging of the local immune privilege may be detrimental to the developing fetus. These findings may also lead to new insights into the pathophysiology of preeclampsia.

Corticotropin Releasing Factor Peptides in the Vascular Endothelium

Multiple reports support the hypothesis that the urocortins, acting via the CRF2 receptors, suppress

locally produced inflammatory responses, the main cause of arteriosclerosis. Indeed, the CRF2 receptors are highly expressed throughout the human cardiovascular system. Interestingly, urocortins and the CRF2 receptor are also highly expressed by the endothelial cells of coronary arteries. Statins, the anti-cholesterol medications, induce the expression of vascular endothelium urocortins and their receptors. The infusion of urocortins affects human vasculature in several ways. They cause a potent vasodilation in an endothelium-independent manner. They protect cardiomyocytes during inflammation of the coronary vasculature via the suppression of angiotensin II-induced reactive-oxygen-species production from vascular endothelial cells. Urocortins also inhibit the apoptosis of mesenteric arterial smooth muscle cells via L-type calcium channels in spontaneously hypertensive rats.

Corticotropin Releasing Factor Peptides in the Heart

Urocortin 1, urocortin 3, and the CRF2 receptor are expressed in human heart. Urocortins, via the CRF2 receptor, have multiple and potent cardioprotective effects. They have an anti-apoptotic effect on cardiomyocytes. More specifically, following cardioplegic arrest and subsequent reperfusion of hearts, cardiomyocytes die from apoptosis through mitochondrial injury. Urocortins protect cardiomyocytes from mitochondrial-mediated apoptosis. Urocortins also protect the ischemia-reperfusion injury of the heart muscle by inhibiting free radical activity. Finally, the infusion of urocortins ameliorates the hemodynamic, hormonal, and renal changes that occur during heart failure.

CRF cardiomyocyte apoptosis Apoptosis contributes to myocyte cell loss in a variety of cardiac pathologies, including cardiac failure and pathologies related to ischemia/reperfusion injury. The apoptotic process involves pro- and anti-apoptotic proteins. Indeed, apoptosis occurs when the equilibrium between pro- and anti-apoptotic mediators is disturbed. Cardiac urocortin expression is enhanced by ischemia/reperfusion injury *in vitro*, and the addition of exogenous urocortins reduces cell death caused by ischemia/reperfusion. In the isolated perfused heart, urocortins improve hemodynamic recovery and partially prevent the reduction in high-energy phosphates following ischemia/reperfusion. It now appears that cardiac urocortins may play a central role in cardiac myocyte protection against iatrogenic ischemia/reperfusion injury associated with bypass surgery. Indeed, it is now obvious that synthetic CRF2 receptor agonists may be extremely important

in cardioplegic therapies, ischemia/reperfusion, and heart failure.

Corticotropin Releasing Factor Peptides in the Skin

A brain–skin connection with local neuroimmunoenocrine circuitry underlies the pathogenesis of allergic and inflammatory skin diseases triggered or aggravated by stress. CRF and the urocortins, along with other neuropeptides, represent part of the brain–skin connection. CRF peptides are produced in the skin, and their production is regulated by ultraviolet radiation, glucocorticoids, and the phase of hair cycle. The skin also expresses the CRF1 and CRF2. CRF1 is expressed in the epidermal and dermal compartments, whereas CRF2 is predominantly expressed in dermal structures. CRF affects several physiological parameters of epidermal melanocytes via the CRF1 receptor. Most prominently, CRF acts on epidermal melanocytes as a survival, anti-apoptotic factor under the stress of starvation as well as an inhibitor of growth factor-induced cell proliferation.

Skin disorders CRF has been implicated in the pathogenesis of skin disorders exacerbated by stress. Indeed, CRF induces skin vascular permeability through neurotensin acting on mast cells. High levels of the CRF1 receptor transcript have been found in the inflammatory lesions of contact dermatitis and chronic urticaria. It should be noted that the local application of CRF on skin reduces the inflammatory and hyperalgesic processes following a vesicant-induced skin injury. CRF has been implicated in the development of acne, seborrhea, androgenetic alopecia, skin aging, xerosis, and other skin disorders associated with alterations in lipid formation of sebaceous origin. CRF has been also found to play a role in the development of psoriasis.

Corticotropin Releasing Factor Peptides in Muscle Inflammation

Fibromyalgia CRF peptides may play a role in muscle physiology and in the inflammatory phenomena taking place in this tissue. Fibromyalgia (FMS) is a debilitating disorder characterized by chronic diffuse muscle pain, fatigue, sleep disturbance, depression, and skin sensitivity. There are no genetic or biochemical markers, and patients often present with other comorbid diseases, such as migraines, interstitial cystitis, and irritable bowel syndrome. Diagnosis includes the presence of 11/18 trigger points, but many patients with early symptoms might not fit this definition. Pathogenesis is still unknown, but there has been evidence of increased CRF and

substance P (SP) in the cerebrospinal fluid (CSF) of FMS patients, as well as increased SP, IL-6, and IL-8 in their serum. Increased numbers of activated mast cells were also noted in skin biopsies. The hypothesis was put forward that FMS is a neuroimmunoendocrine disorder in which increased release of CRF and SP from neurons in specific muscle sites triggers local mast cells to release pro-inflammatory and neurosensitizing molecules. There is no curative treatment, although low doses of tricyclic antidepressants and the serotonin-3 receptor antagonist tropisetron are helpful. Recently, new formulations containing the natural anti-inflammatory and mast cell-inhibitory flavonoid quercetin may hold promise as therapeutic agents.

Muscle thermogenesis CRF may also induce skeletal muscle thermogenesis (i.e., loss of energy as heat), protecting patients against excessive intramyocellular lipid storage and hence against skeletal muscle lipotoxicity, local inflammation, and, most important, the all-important development of insulin resistance. Finally, the administration of synthetic CRF2 receptor agonists may hold promise as a treatment for the prevention of skeletal muscle atrophy.

Corticotropin Releasing Factor Antagonists as New Therapeutic Agents of Inflammatory Diseases

The CRF system has been implicated in the pathophysiology of a variety of diseases, including depression, epilepsy, addiction, and Alzheimer's. The CRF system has been also shown to play an important role in GI disorders. During the last decade, an important effort was made to develop nonpeptide micromolecular antagonists of CRF receptors with potential therapeutic applications in the treatment of several of these diseases. These, low-molecular-weight, non-peptide CRF antagonists belong to four main classes of molecules: monocyclic, bicyclic, and tricyclic compounds and a miscellaneous category that includes compounds that are unlike the traditional small-molecule CRF antagonists.

In addition to the promising therapeutic role that nonpeptide CRF1 antagonists may have for the treatment of CNS-related diseases, these molecules may be useful in the treatment of localized chronic inflammation in several systems. For instance, these compounds open new therapeutic options in the control of lower-GI inflammatory conditions associated to CRF, such as chronic inflammatory bowel syndromes and irritable bowel syndrome. On the other hand, urocortin or synthetic micromolecular CRF2 agonists may be useful in the treatment of upper-GI

inflammatory diseases. Similarly, in reproduction, because CRF1 blockade appears to prevent implantation by reducing the inflammatory reaction of endometrium to the invading blastocyst, CRF1 antagonists may play a role as a new class of nonsteroidal inhibitors of implantation. Given the promising future of CRF antagonists in the therapy of depression and anxiety disorders, their ability to cause hypofertility and early miscarriages should seriously be borne in mind in prescribing these compounds.

Synthetic CRF2 receptor agonists may be extremely important in cardioplegic therapies, ischemia/reperfusion, and heart failure, protecting against iatrogenic ischemia/reperfusion injury associated with bypass surgery. Finally, the administration of synthetic CRF2 receptor agonists may hold promise as a treatment preventing skeletal muscle atrophy.

Introduction

Corticotropin Releasing Factor Receptor Family

Pharmacological Characteristics

Distribution of Corticotropin Releasing Factor Receptor Subtypes

Summary and Conclusion

Glossary

Adenylate cyclase

One of the signaling molecules for G-protein-coupled receptors. On activation by a specific G-protein, this transmembrane protein either increases or decreases the rate of conversion of ATP to cAMP.

Corticotropin releasing factor (CRF)

A 41-amino-acid peptide primarily secreted by the hypothalamus into the hypophyseal portal vasculature to act on the pituitary and cause the release of adrenocorticotrophic hormone.

G-protein

A heterotrimeric protein that has high affinity for GTP and interacts with the cytoplasmic domains of a receptor, transducing the signal from the activated (ligand-bound) receptor to the second-messenger signaling protein inside the cell.

G-protein-coupled receptor

A protein that typically spans a cell membrane seven times with extracellular and intracellular loops coordinating the binding of a ligand outside the membrane with a signal transduction mechanism inside the membrane.

Hypothalamic-pituitary-adrenal (HPA) axis

The hormonal pathway that is thought to mediate the primary stress response. CRF secreted from the hypothalamus acts on the anterior pituitary to release adrenocorticotrophic hormone (ACTH), which in turn acts on the adrenals to produce and release glucocorticoids. Glucocorticoids feed back to the pituitary to decrease ACTH release and also act on the hypothalamus to decrease CRF release in a negative feedback loop.

Introduction

More than half a century ago, Geoffrey Harris first proposed the concept that the hypothalamus plays a primary role in the regulation of the pituitary-adrenocortical axis and extended the notion put forth by Walter B. Cannon that an organism's ability to maintain homeostasis in the face of external stressors was coordinated by a specific portion of the central nervous system (CNS) operating in an automatic fashion. Subsequently, during the 1950s, Guillemin and Rosenberg and Saffran and Schally independently observed the presence of a factor in extracts of the hypothalamus that could stimulate the release of adrenocorticotrophic hormone (ACTH, corticotropin) from anterior pituitary cells *in vitro*. This extract was termed corticotropin releasing factor (CRF). Although CRF was the first hypothalamic hypophysiotropic factor to be recognized, its chemical identity remained unknown largely due to the presence in hypothalamic extracts of other weaker secretagogues of ACTH secretion such as vasopressin, catecholamines, and angiotensin II. These agents, along with their synergistic effects with CRF on ACTH secretion and in combination with the relative lack of specificity of the *in vitro* bioassays, hindered the purification of this peptide. The development of radioimmunoassays for ACTH and quantitative

in vitro methods for assaying hypophysiotropic substances along with the use of ion exchange and high-performance liquid chromatographic techniques led to the successful purification of CRF from sheep hypothalamic extracts in 1981 by Vale and his colleagues at the Salk Institute. They were the first to report the isolation, characterization, synthesis, and *in vitro* and *in vivo* biological activities of a 41-amino-acid hypothalamic peptide that fulfilled all the criteria for a corticotropin releasing factor. Thus, from the first basic understanding of homeostasis in the early 1940s, this neuropeptide has gained widespread acknowledgement of its role in mediating the HPA axis and regulating an organism's response to physical, emotional, and environmental stress.

Since the elucidation of the structure of CRF, there have been countless studies that have demonstrated the importance of this peptide and its role as a neurotransmitter and neuromodulator in the CNS apart from its role in the direct stimulation of ACTH from the pituitary through hypothalamic release. These reports have detailed the anatomical distribution of both CRF-containing cell bodies and fibers in the CNS and have identified the peptide in regions of the brain shown to clearly regulate autonomic function and mediate the behavioral responses to stress. For example, the neocortex contains high densities of CRF-containing neurons that are localized primarily to prefrontal, cingulate, and insular areas and that appear to regulate behavioral actions of the peptide. This extrahypothalamic distribution of CRF suggests that this peptide has numerous effects in the brain, and its widespread but discrete localization in various brain regions, both rat and human, place it in a position to regulate mood and stress-related behaviors. In fact, the exogenous administration of CRF into discrete brain regions has demonstrated direct interactions between the CRF and the norepinephrine systems (such as in the locus coeruleus) or the serotonergic systems (such as in the dorsal and median raphe nuclei) and corresponds to the effects seen under various stress paradigms in which these systems are activated. This further implicates this particular neuropeptide in mediating the central mechanisms through which various stressors can alter behavior.

The relatively recent cloning of multiple CRF receptor subtypes and the identification of a specific binding protein for the peptide (known as CRF-BP) has precipitated a new era in CRF research. In addition, the identification of a new related family of endogenous peptides, the urocortins, has expanded the notion that this system is under multiple regulatory factors and plays a much more complex role in the CNS than previously thought. This article focuses primarily on recent studies that elucidate the molecular

biological, pharmacological, anatomical, and functional characteristics of mammalian CRF receptors.

Corticotropin Releasing Factor Receptor Family

Molecular Biology/Receptor Structure

The CRF receptors belong to the superfamily of G-protein-coupled receptors and, as such, have been shown to contain seven putative transmembrane domains and function through the coupling of a stimulatory guanine-nucleotide binding protein. These receptors also fall within the recently described, and still-growing, family of gut-brain neuropeptide receptors, which includes receptors for calcitonin, vasoactive intestinal peptide (VIP), parathyroid hormone, secretin, pituitary adenylate cyclase-activating peptide, glucagon and growth hormone-releasing factor. These receptors all share considerable sequence homology, and all stimulate adenylate cyclase in response to their respective agonist activation. Almost all of the initial characterization of the CRF receptors was performed using various native tissues from a variety of species. As such, there was only one form of the receptor that could be experimentally discerned. As will be described later in the chapter, this form was subsequently identified as the CRF₁ receptor. It has been very difficult to pharmacologically study the CRF₂ receptor in native tissues due to its discrete localization and relatively low abundance. Cloning of these receptor subtypes however, has enabled the pharmacological and biochemical characterization of these proteins and allowed the discovery of potential therapeutics through a variety of chemical-screening strategies.

CRF₁ Receptors

Vale and colleagues first cloned the CRF₁ receptor in 1993 from a human Cushing's anterior pituitary corticotrophic adenoma using the technique of expression cloning. The protein was characterized as a 415-amino-acid protein with seven putative transmembrane domains and five potential extracellular N-linked glycosylation sites. In addition, the protein contained putative sites for protein kinase C phosphorylation in the first and second intracellular loops and in the C-terminal tail, as well as casein kinase II and protein kinase A phosphorylation sites in the third intracellular loop. The human gene was subsequently localized on chromosome 17 at position 17q12–22. Shortly after the elucidation of this human form, several groups identified the CRF₁ form of the receptor from a variety of other species. All species of CRF₁ mRNAs thus far identified encode proteins of 415

amino acids that are 98% identical to one another. The human CRF₁ gene contains at least two introns and is found in a number of alternative splice forms, none of which to date has been found to have any physiological significance. This is in contrast to the mouse, in which the gene has been identified as containing at least 12 introns. The various kinase and phosphorylation sites predicted on these proteins, although not fully characterized, may serve as regulatory elements in the control of receptor expression and/or function. The potential N-linked glycosylation sites on the N-terminal extracellular domain are characteristic of most G-protein-coupled receptors and confirm the glycosylation profiles determined by earlier chemical-affinity cross-linking studies. Indeed, the molecular weight predicted from the deglycosylated forms of the CRF₁ in the earlier biochemical studies was virtually identical to that obtained from the cloned amino acid sequence. Furthermore, mRNA distribution of the CRF₁ in the rat or human brain correlates extremely well with the previously identified binding sites for radiolabeled CRF using autoradiographic techniques in frozen brain sections. This correlation was expected (retrospectively) because the peptide CRF itself has a low affinity for the CRF₂ and does therefore not label this subtype in brain sections to any detectable level. There have been reports in the literature of splice variants of the CRF₁ mRNA; however, these have not yet been shown to produce physiologically functional proteins. This does not preclude the notion that splice variants of the CRF₁ may exist; however, their full characterization will have to await functional elucidation in a native tissue.

CRF₂ Receptors

Shortly after the cloning and characterization of the CRF₁, another subtype of this family for this hormone was identified through homology. This receptor constituted the CRF₂ subtype of the family and initially represented two splice forms termed CRF_{2(a)} and CRF_{2(b)}. The CRF_{2(a)}, originally described by Lovenberg et al., is a 411-amino-acid protein with approximately 71% identity to the CRF₁. The CRF_{2(b)}, which has been cloned from rat, mouse, and human, contains 431 amino acids and differs from the CRF_{2(b)} isoform in that the first 34 amino acids in the N-terminal extracellular domain are replaced by a unique sequence, 54 amino acids in length. The CRF_{2c} has most recently been identified and, thus far, is found only in the human brain. This splice variant uses yet a different 5' alternative exon for its N-terminus and replaces the first 34-amino-acid sequence of the CRF_{2(a)} with a unique 20-amino-acid sequence.

Between the CRF₁ and CRF_{2s}, there exist very large regions of amino acid identity, particularly between transmembrane domain five and transmembrane domain six. This similarity strongly argues for conservation of biochemical function because it is this region that is thought to be the primary site of G-protein coupling and signal transduction. All three CRF₂ Receptors contain five potential N-glycosylation sites, which are analogous to those found on the CRF₁. The genomic structure of the human CRF₂ gene is similar to that of the mouse CRF₁, already described, and has 12 introns, the last 10 of which interrupt the coding region in identical positions. These gene sequences, however, diverge significantly at the 5' end. The chromosomal mapping of the human CRF₂ gene has been localized to chromosome 7 p21-p15.

Endogenous Ligands

The peptide structure of CRF, once the amino acid sequence was determined, was found to bear strong similarities to two nonmammalian peptides, sauvagine from the frog and urotensin I from the fish. All of these peptides have the ability to potently release ACTH from cultured rat pituitary cells, which identifies them as high-affinity agonists for CRF Receptors. Although the mammalian CRF peptides from a variety of species all had high affinity for the CRF₁, they had lower affinity for the CRF₂, creating some doubt as to the likelihood that these peptides were the physiological activators for the CRF₂. It was interesting and quite unexpected, however, that, in addition to their high affinity for the CRF₁, the nonmammalian peptides sauvagine and urotensin I also had a high affinity for the CRF₂. In 1995, using antibodies for urotensin I, the first of a unique and novel family of mammalian peptides related to CRF was discovered in the rat and termed urocortin (UCN)1. UCN1 had a high affinity for both CRF Receptor subtypes, also bound with high affinity to the CRF-BP, and was localized in areas corresponding to the distribution of the CRF₂ itself. The human homolog of UCN was later identified and cloned from a human brain library and defined as the endogenous ligand for the CRF₂. Since then, two other mammalian peptides have been identified from the mouse and human, termed UCN2 (also referred to as stresscopin-related peptide) and UCN3 (also referred to as stresscopin). Unlike UCN1, UCN2 and UCN3 are much more selective for the CRF₂ subtype and have little or no affinity for the CRF-BP. These peptides have enabled a greater understanding of this increasingly complex system in the regulation of central stress responses.

To date, there are no known endogenous physiological antagonists for the CRF Receptor system;

however, various truncations of the agonist peptides, with deletions of the first 8–11 N-terminal amino acids, have resulted in potent peptide antagonists. Of these, α -helical CRF(9–41), d-Phe CRF(12–41), and astressin are among the most potent and well characterized, having a high affinity for both the CRF₁ and CRF₂ receptors and being able to functionally block receptor activity both *in vitro* and *in vivo*. Recently, chemical modifications have resulted in two additional peptides that now have 400- to 500-fold selectivity for the CRF₂ over the CRF₁. Antisauvagine-30, an N-terminally truncated form of sauvagine, and the more recent cyclized astressin-2B have been used to dissect out specific roles of the CRF₂ subtype in a variety of *in vivo* studies. The pharmacological profiles of these peptide agonists and antagonists have elucidated some of the discrete biochemical requirements of the two receptor subtypes and have greatly enhanced the understanding of the physiology of the CRF system and the important role this neurohormone plays in mediating the stress response. Furthermore, there is now increasing evidence that this system is fully integrated in diseases such as anxiety and depression and may provide a target for novel therapeutics in the treatment of these disorders.

Pharmacological Characteristics

The rat and human forms of the CRF Receptor family have been transfected into a variety of mammalian cell lines that do not normally express these receptors, including COS-7 (monkey kidney), CHO (Chinese hamster ovary), and Ltk⁻ (mouse fibroblast) cells. Although rat tissue was commonly available for the study of the CRF₁, the expression in stable mammalian cell lines of the human forms of the CRF Receptor subtypes enabled, for the first time, direct biochemical and pharmacological study without the requirement for scarce human brain tissue.

The CRF Receptor subtypes exhibit a clear and distinct pharmacological profile with respect to the endogenous and related peptides known to activate this system. In addition, the CRF_{2(a)} and CRF_{2(b)} display very subtle differences in the pharmacological profiles with respect to one another, which suggests that some specific conformation of the protein can be attributed to the N-terminal extracellular domains and is critical for the high-affinity binding of peptides. As a direct result of the distinct pharmacological difference between the CRF₁ and CRF₂ subtypes, it became necessary to radiolabel a nonmammalian CRF-like ligand ([¹²⁵I]sauvagine) in order to completely characterize the CRF₂ subtype. Previous studies examining the detailed binding characteristics of the CRF peptides with respect to the peptide structure have revealed

that all the CRF peptides – be they agonist or antagonist – must be amidated at their C-terminus for potent activity. The deamidation of any of these peptides results in a virtually complete loss of activity at either receptor subtype, suggesting that at least some similarity between the two subtypes must exist.

Ligand Binding Profile of CRF₁ Receptors

CRF₁ receptors expressed in the mammalian cell lines described demonstrate reversible, saturable, high-affinity binding to CRF and its related peptides with the pharmacological and functional characteristics comparable to those found in the variety of animal or human tissues previously described in the literature. Human and rat CRF₁ receptors in stably transfected Ltk⁻ cells demonstrate binding to a single homogeneous population of receptors with apparent affinities (K_D) of 130 and 168 pM and receptor densities (B_{max}) of 97 and 588 fmol/mg protein, respectively. The pharmacological rank orders of potency in the stably transfected cell lines with either the human or rat CRF₁ receptors were identical to the established profile for the CRF receptor in the rat frontal cortex, where UCN1, urotensin I, sauvagine > ovine CRF (oCRF), rat/human CRF (r/hCRF), bovine CRF > astressin > D-Phe r/hCRF(12–41) > α -helical oCRF(9–41) $\gg$ UCN2, UCN3, astressin-2B, r/hCRF(6–33), r/hCRF(9–33), r/hCRF(1–41)OH, VIP, arginine vasopressin (AVP). These data demonstrate that, although there are subtle differences between the rat and human forms of the receptor in terms of amino acid sequence, the differences are not significant enough to alter the ability of these peptides to bind or interact with this subtype.

Ligand Binding Profile of CRF₂ Receptors

The CRF₂ isoforms have also been expressed in stable mammalian cell lines and demonstrated to bind CRF-related peptides and function through the stimulation of cAMP production. In general, although some minor differences exist in the rank order profile of the CRF₂ splice variants to one another (mainly related to fragments of CRF peptides), as a subtype they are quite distinct from either the CRF₁ subtype or the CRF-BP. When expressed in stable cell lines, these receptors exhibit the following pharmacological rank order profile: UCN1, UCN2, sauvagine, urotensin I, astressin-2B > UCN3 > astressin > r/hCRF > D-Phe CRF(12–41), α -helical CRF(9–41) $\gg$ oCRF $\gg$ r/hCRF(6–33), oCRF(6–33), r/hCRF(1–41)OH, GHRH, AVP, and VIP. The data thus far on the CRF_{2(a)} suggests a rank order of potencies similar to the other two splice variants with UCN, sauvagine > urotensin I > r/hCRF. Without exception, it is

clear that the mammalian CRF peptides oCRF and r/hCRF have weaker affinity for the CRF₂ subtype, whereas UCN has equal affinity for both the CRF₁ and CRF₂ receptors and UCN2 has selectivity for the CRF₂ receptors. Interestingly, the relatively weaker affinity of UCN3 for the CRF₂ receptors may indeed suggest that this peptide is the endogenous ligand for a different and thus far undiscovered CRF receptor subtype.

Guanine Nucleotide Characteristics of Corticotropin Releasing Factor Receptors

Characteristic of receptor systems that are coupled to adenylate cyclase as a second-messenger system is the exclusive link to a guanine nucleotide-binding protein. These transducing proteins mediate the ligand-binding event at the receptor to an activation of an intracellular pathway, in this case beginning with the conversion of ATP to cAMP. *In vitro*, guanine nucleotides have been shown to decrease the specific binding of agonists for a great number of seven-transmembrane neurohormone or neurotransmitter receptors coupled to G-proteins, presumably by uncoupling the G-protein from the receptor and changing its conformation such that it now has low affinity for its agonist. Both CRF receptor subtypes transfected in stable mammalian cell lines were used to determine the guanine nucleotide sensitivity of the cloned receptors. Guanine nucleotides inhibited the binding of [¹²⁵I] oCRF (for CRF₁ receptors) or [¹²⁵I]sauvagine (for either CRF₁ receptors or CRF₂ receptors) by 50–70% (where 100% inhibition was defined by 1 μ M unlabeled r/hCRF). The nonhydrolyzable forms of guanine nucleotides, Gpp(NH)p and GTP- γ -S, were more potent than GTP itself. The order of potencies were GTP- γ -S > Gpp(NH)p > GTP with median effective dose (ED₅₀) values of ~20–45, 200–800 and 2500–3000 nM, respectively. These effects on the binding in both human and rat CRF₁- or CRF₂-stable cell lines were specific for the guanine nucleotides because the adenosine nucleotide ATP was ineffective in altering the binding at equimolar concentrations (ED₅₀ > 10 000 nM). Recently, using a variety of peptide ligands in conjunction with the guanine nucleotide GTP- γ -S, three distinct receptor states have been elucidated for the CRF₁. These states represent RG, the G-protein-coupled form of the receptor sensitive to guanine nucleotides; R, the G-protein-uncoupled form of the receptor; and R0, a high-affinity uncoupled state of the CRF₁ that is GTP- γ -S insensitive. Although the nature of this state requires much further investigation for the CRF system, this conformation has been described for other GPCRs, including the β_2 -adrenergic, M2 muscarinic, formyl peptide, and natural killer (NK)1 cell receptors where

they have been identified to be in a complex with arrestin. Significantly, these three states for the CRF₁ have also been confirmed to exist in native rat tissues such as the cerebellum and may offer new approaches for the discovery of molecules targeting conformationally restricted binding sites.

Second-Messenger Characteristics of Corticotropin Releasing Factor Receptors

In addition to the adenylate cyclase system, other signal transduction mechanisms have been postulated to be involved in the actions of CRF. For example, CRF has been shown to increase protein carboxyl-methylation and phospholipid methylation in AtT-20 cells. Preliminary evidence suggests that CRF may regulate cellular responses through products of arachidonic acid metabolism. Furthermore, although the evidence in anterior pituitary cells suggests that CRF does not directly regulate phosphatidylinositol turnover or protein kinase C activity, the stimulation of protein kinase C, either directly or by specific ligands (vasopressin or angiotensin II), enhances CRF-stimulated adenylate cyclase activity, ACTH release, and inhibits phosphodiesterase activity. Thus, the effects of CRF in native tissues such as the anterior pituitary cells, neurons, and other cell types expressing CRF receptors are likely to involve complex interactions among several intracellular second-messenger systems. All this evidence has thus far been gathered from native tissues that exhibit binding profiles consistent with the CRF receptor. These studies have most probably been examining second-messenger profiles of the CRF₁ in various tissues, primarily due to the ubiquitous nature of this subtype compared to the CRF₂ in the rat. Clearly, the most common and well-studied second-messenger system for the CRF receptor is the coupling to the adenylate cyclase system. In fact, there is no evidence to date that the heterologous expression of hCRF receptors transfected into mammalian cells function in any manner other than through the stimulation of the production of cAMP, unless forced to couple through overexpressed, genetically manipulated cell systems.

In the pituitary gland, CRF initiates a cascade of enzymatic reactions, beginning with the receptor-mediated stimulation of adenylate cyclase, which ultimately regulates proopiomelanocortin (POMC) peptide secretion and possibly synthesis. POMC-derived peptide secretion mediated by the activation of adenylate cyclase is dose-related and exhibits appropriate pharmacology consistent with the activation of the CRF₁. Similarly, in the brain and also in spleen, the pharmacological rank order profile of CRF-related peptides for stimulation of adenylate cyclase is analogous to the profile seen in the pituitary

and in keeping with the affinities of these compounds for receptor binding. In addition, the putative CRF receptor antagonist α -helical oCRF(9–41) inhibits the CRF-stimulated adenylate cyclase observed in brain and spleen homogenates.

To further characterize the stable CRF receptor transfectants, the ability of CRF-related and unrelated peptides to stimulate CRF₁- or CRF₂-mediated cAMP production from the cells has been examined. The rank order of the peptides in stimulating cAMP production in these cells was in keeping with their rank order in inhibiting [¹²⁵I]oCRF and [¹²⁵I]sauvagine binding to the CRF₁ and CRF₂, respectively, and at least for the CRF₁, this rank order was virtually identical to the second-messenger pharmacological profile previously reported in the brain, pituitary, and spleen.

In addition to the stimulation studies, CRF-stimulated cAMP production could be competitively inhibited by the putative peptide antagonists D-Phe CRF(12–41) and α -helical CRF(9–41) in both CRF₁- and CRF₂-expressing cell lines, demonstrating that the expressed CRF receptors in these cell lines were indeed functional. Interestingly, both D-Phe CRF(12–41) and α -helical CRF(9–41) inhibited the stimulated cAMP response with the same median effective concentration (EC₅₀) in both receptor subtype preparations. This suggests that, although there is some fundamental difference in the pharmacological specificity of these two receptor subtypes when examining agonists, they must still possess some similarities in their structure of the binding site, at least as far as peptide antagonists are concerned. These results clearly suggest that not only subtype-specific and subtype-selective compounds can be identified for these two receptor subtypes but that mixed antagonists are possible and could bring to light possible subtle functions of the two receptor subtypes.

Distribution of Corticotropin Releasing Factor Receptor Subtypes

Receptor autoradiographic studies and more recent *in situ* hybridization and immunocytochemical studies have localized CRF binding sites and CRF Receptor mRNA, respectively, in slide-mounted sections of many tissues from a variety of species, identifying these proteins in anatomically and physiologically relevant areas. For example, in the pituitary gland, CRF₁ expression is detectable in both the anterior and intermediate lobes, with particularly high expression in clusters within the anterior lobe. In fact, there exists a good correlation between the actions of CRF on corticotropes of the anterior pituitary and the distribution of [¹²⁵I]oCRF or [¹²⁵I]sauvagine binding sites and CRF₁ mRNA. Within the anterior

lobe, CRF₂ expression is detectable in only a few scattered cells. Thus, in terms of HPA axis activity, CRF₂ receptors may mediate CRF effects at the level of the hypothalamus, whereas CRF₁ receptors are responsible for CRF-induced changes in ACTH release in pituitary corticotropes.

Although there is a general correspondence of the distribution of [¹²⁵I]oCRF or [¹²⁵I]sauvagine binding sites and CRF₁ or CRF₂ mRNA in the brain with the functional actions of CRF, there are several brain areas with some apparent discrepancies. For example, CRF has potent electrophysiological and behavioral effects in the locus coeruleus, but the distribution of binding sites and CRF₁ or CRF₂ mRNA is not noteworthy in this brain-stem nucleus. Physiologically, it is tempting to speculate that other subtypes that are as yet unidentified may be responsible for the actions of the neurotransmitter in those regions where CRF seems to have profound actions but no appreciable labeling of the receptor is observed. The localization and distribution of CRF₂ Receptors in the mammalian brain, coupled with the discovery of the urocortins, has accounted for some of these discrepancies. However, species differences in the localization of receptor subtypes and peptides among rodent, non-human primate, and human tissues have made it somewhat difficult to extrapolate behavioral studies in rodent models to human effects. It is important to note that, because most of the autoradiographic studies in the literature thus far in rodents have used [¹²⁵I]oCRF or various forms of [¹²⁵I]rat/human CRF, the primary labeling, localization, and distribution are almost exclusively attributable to the CRF₁ subtype.

Within the rat brain, CRF₁ expression was very high in neocortical, cerebellar, and sensory relay structures, whereas CRF₂ expression was generally confined to subcortical structures, including the lateral septal region, the bed nucleus of the stria terminalis, the amygdaloid area, and the olfactory bulb. The contrast in expression patterns between CRF Receptor subtypes was particularly evident within the septal region; CRF₂ mRNA expression was very high in the lateral septal nuclei but very low in the medial septum, a region where CRF₁ mRNA abundance was most evident. The lateral septum, by virtue of widespread reciprocal connections throughout the brain, is implicated in a variety of physiological processes. These range from higher cognitive functions, such as learning and memory, to autonomic regulation, including food and water intake. In addition, the septum plays a central role in classic limbic circuitry and is thus important in a variety of emotional conditions, including fear and aggression. The lateral septum thus acts as both an integrator of limbic circuitry and an interface between the telencephalic and diencephalic

areas. The high-level of CRF₂ expression in this area suggests a role for CRF₂ Receptors in modulating limbic circuitry at the level of the lateral septum.

The heterogeneous distribution of CRF₁ and CRF₂ mRNA suggests distinctive functional roles for each receptor in CRF-related systems. CRF₂ mRNA was evident throughout the rostrocaudal extent of the hypothalamus, particularly within the paraventricular nucleus (PVN), whereas CRF₁ expression was limited. The distribution of cells expressing CRF₂ mRNA within the PVN coincides with the cellular distribution of CRF mRNA, suggesting a possible autoreceptor role for CRF₂ Receptors in this nucleus. Because the CRF neurons of the PVN play a classical hypophysiotropic role in controlling ACTH release from the anterior pituitary, it is tempting to speculate that CRF₂ Receptors may act to selectively regulate hypophysiotropic-and/or autonomic-related CRF neurons. As such, this receptor subtype may be central to the control of the mammalian HPA stress system. Further, more detailed studies using double-labeling of the peptides and their receptors are required to determine the discrete role of this subtype. Whatever the case may be, the high level of CRF₂ expression within the hypothalamic structures is certainly suggestive of a role for CRF₂ Receptors in modulating autonomic CRF neurons. With regard to HPA axis activity, we may speculate that the PVN CRF₂ Receptors could also act to modulate CRF neurosecretory neurons in response to stress, in essence providing a short-loop feedback role. Ono and colleagues have proposed such a role for CRF in a positive ultrashort-loop feedback effect on stress-induced ACTH release. In this regard, the comparatively lower affinity of CRF for the CRF₂ subtype may be of physiological design to allow activation of CRF₂ Receptors only under conditions of chronic stress or prolonged CRF release.

A more detailed examination of the precise localization of the CRF₂ splice variants, CRF_{2(a)} and CRF_{2(b)}, indicates discrete anatomical distributions in the rat. The CRF_{2(a)} form is primarily expressed within the brain, whereas the CRF_{2(b)} variant is localized in both the CNS and periphery. Within the brain, it appears that the CRF_{2(a)} form represents the predominant neuronal CRF₂ variant, whereas the CRF_{2(b)} splice form is localized on nonneuronal elements, such as the choroid plexus of the ventricular system and cerebral arterioles. In the periphery, CRF_{2(b)} mRNA is expressed at high levels in both the cardiac and skeletal muscle, with lower levels evident in both the lung and intestine. The CRF_{2(c)} isoform has yet to be identified in the rodent; however, reverse transcription polymerase chain reaction (RT-PCR) analysis of human brain mRNA demonstrated expression in the

septum, amygdala and hippocampus, and frontal cortex. The full characterization of the CRF_{2(c)} subtype has not yet been elucidated in terms of native characteristics and function largely due to its nonexistence in rodent tissues. This type of species selectivity will make it difficult to completely examine the role of the CRF₂ subtype unless suitable animal models can be found.

Finally, in addition to the expression in the CNS, CRF receptors have been localized to a number of peripheral tissues. The gastrointestinal (GI) tract is an organ system that has a discrete localization pattern of CRF₁ and CRF₂ and is sensitive to a variety of stressors thought to act via the CRF system, both centrally and peripherally. GI responses are differentially affected by stress and these can be reproduced by the central administration of CRF. For example, stress decreases gastric emptying (upper GI tract) while increasing colonic motility and transit (lower GI tract). These effects seem to be independent of the HPA response and most likely reflect central autonomic function mediated by central CRF₂ and CRF₁, respectively. The fact that both these receptor subtypes are also found throughout the stomach and bowel, including the colon, suggests a much more complex interaction of this stress response system in the gut and that the precise mechanisms of regulation remain to be elucidated.

Summary and Conclusion

CRF is the primary regulator of the endocrine, autonomic, and behavioral response to stress via mechanisms in both the brain and the periphery. The endocrine stress response begins with the activation of the HPA axis, resulting in the release of CRF into the hypophysial portal vasculature. CRF then mediates its actions through cell surface receptors coupled to the activation of adenylyl cyclase. Centrally, CRF is found throughout the brain and plays a major role in mediating emotional, psychological, or behavioral stress. As described here, CRF receptors can be classified into two distinct subtypes: the CRF₁ (411 amino acids) and CRF₂, with the latter comprising three different isoforms, CRF_{2(a)}, CRF_{2(b)}, and CRF_{2(c)} (encoded by 415, 431, and 397 amino acid proteins, respectively). These receptors differ with respect to their structures, tissue distributions, and pharmacological specificities for CRF-related ligands. UCN1, a mammalian CRF-related peptide with close sequence homology to fish urotensin, interacts with a high affinity with all CRF receptors, whereas UCN2 and UCN3 are more selective for the CRF₂ subtype. The areas of distribution of these CRF receptors in the brain are correlated well with the

immunocytochemical distribution of the CRF and urocortin pathways as well as the pharmacological sites of action of CRF and the urocortins. The species differences that exist with respect to the distinct subtypes of the CRF₂ precludes our complete correlation of animal studies with humans; however, the identification of the multiple subtypes has led to an enhanced understanding of this complex system. It is becoming increasingly clear that the multiple receptor subtypes must mediate different functional and pathophysiological actions of this family of neuropeptides, and future studies aimed at identifying additional subtypes or peptides will serve to fully elucidate the role of this key neurohormone in the pathophysiology of stress and stress-related disorders.

Conclusion

Glossary

Area under the curve A method of estimating aggregate cortisol output from a series of timed samples. It is typically calculated by assuming that the secretion rate is uniform across the time period. For example, if the salivary cortisol level is 18.0 nmol/liter at T_1 , 22.0 at T_2 (14 min later), and 26.0 at T_3 (20 min after T_2), the area under the curve is calculated as $((18.0 + 22.0) / 2) \cdot 14 + ((22.0 + 26.0) / 2) \cdot 20 = 760.0$.

Carotid intima-media thickness The depth of the intima-medial layer of the wall of the carotid arteries, assessed noninvasively using duplex ultrasonography. This is an index of subclinical atherosclerosis and correlates with coronary artery disease.

Cortisol awakening response (CAR) The increase in cortisol during the first hour after waking up, typically peaking at 20–40 min after waking.

Definition

The CAR is the change in cortisol concentration that occurs during the first hour after waking from sleep. The CAR has been studied in detail only over the past decade, following the introduction of salivary cortisol sampling. This has allowed people to collect samples noninvasively under normal life conditions at home instead of under the contrived conditions of the sleep or endocrinological laboratory. The CAR is now a topic of intense investigation.

Cortisol levels are low in the night but rise in the early hours before waking. After waking up, most people show a further rise, the concentration peaking 20–40 min later. This is followed by a progressive

reduction of cortisol during the day. There are several reasons why the CAR has become an important research topic. First, there is evidence that the CAR is under somewhat independent control from cortisol output during the remainder of the day. Several studies have shown little association between the CAR and cortisol levels during the rest of the day or the slope of cortisol concentration decline into the evening. Second, twin studies have documented a genetic influence on the CAR that is distinct from the heritability of daytime cortisol levels. Third, the CAR is associated with stress and health in potentially significant ways, suggesting that it is a useful marker of hypothalamic-pituitary-adrenocortical (HPA) function.

A number of different measures of the CAR have been devised, depending on how many saliva samples are obtained over the first hour after waking. Serial sampling suggests that that peak CAR is observed around 30 min after waking, so the simplest method of assessment involves measures at two time points: immediately after waking and 30 min later; the CAR is then defined as a simple difference score. More elaborate assessments involve measurements of several time points, such as immediately after waking and 15, 30, 45, and 60 min later; under these circumstances, the area under the curve can be computed to estimate total cortisol output. Difference scores and area under the curve measures are consistently intercorrelated.

Origins of the Cortisol Awakening Response

The secretion of cortisol is pulsatile, and it has been estimated that each secretory burst induces an increase in salivary free cortisol of approximately 2.5 nmol liter⁻¹. The CAR is a result of one to four secretory bursts over the period following waking. It is consistent across days under stable environmental conditions, but changes in magnitude when conditions vary.

The CAR is sensitive to light in the environment and can be enhanced by augmented light exposure early in the day. It has been proposed that this effect is mediated by the suprachiasmatic nucleus of hypothalamus, which is light sensitive and is involved in circadian regulation. Direct neural connections between the suprachiasmatic nucleus and the adrenal cortex have been identified and may modulate the sensitivity of the adrenal gland to adrenocorticotrophic hormone.

The functional role of the CAR has not been established. It may be important metabolically in mobilizing the organism during the transition from sleep to waking. However, no association between the CAR and blood glucose levels has been observed. A role in immunological regulation has also been suggested, but direct evidence is lacking at present. The relevance of psychological factors is apparent from some studies, and it is further endorsed by the observation that the CAR is abolished in individuals with global amnesia, even though the remainder of the circadian rhythm of cortisol output is retained. This hints at the possibility that the CAR may depend either on recent life experiences or on anticipation of the activities and events of the forthcoming day.

Measurement of the Cortisol Awakening Response

Participants in CAR studies are instructed to take saliva samples immediately after waking and then at later defined intervals. Saliva is collected using cotton rolls or by directly spitting into test tubes, and participants are instructed not to brush their teeth, eat, drink, or smoke throughout the sampling period because these factors can influence cortisol values. Because the CAR is dynamic, accurate timing is critical, and failure to adhere to the sampling schedule may confound studies and produce misleading results. If the waking sample is delayed, the CAR may already have commenced, leading to an apparent diminution in the magnitude of the rise of the next 20–30 min. Similarly, if later samples are mistimed, then the magnitude of the CAR will not be assessed correctly.

The significance of timing errors has been demonstrated using saliva collection devices that are time-stamped. One study showed that more than 50% of community volunteers failed to take the 30-min post-waking sample at the correct time. Noncompliant participants produced smaller CARs. The impact of delays in collecting the waking sample is illustrated in [Figure 1](#). This figure compares salivary cortisol profiles during the first hour of the day in elderly (65- to 80-year-old) volunteers who reported no delay in taking the first sample after waking and those who admitted delaying for 10 min or more. The no delay group showed a typical CAR with increases from waking to 30 min, whereas a decrease during same period was found in the delay group.

Several methods of improving the accuracy and reliability of CAR measurement have been proposed. Electronically time-tagged saliva collection methods provide data about the intervals between measurements, but information about the timing of waking up is still provided by the participants. Asking

Figure 1 Mean salivary cortisol levels immediately after waking and at 10, 20, 30 and 60 minutes after waking in elderly volunteers who delayed (dashed line) and did not delay (solid line) saliva sampling after waking in the morning. Error bars are standard errors of the mean. From Wright, C. E., & Steptoe, A. (2005). Subjective socioeconomic position, gender and cortisol responses to waking in an elderly population. *Psychoneuroendocrinology*, 30, 582–590. Used with permission.

participants to record when they wake and when they take each sample provides a check and limits can be set on acceptable delays, but this method again depends on self-reports. The measurement of waking time using actigraphy is being explored. Another approach is to check for consistency across days and to exclude individuals who show widely discrepant CAR patterns on different days.

Factors Affecting the Cortisol Awakening Response

A wide range of factors potentially affect the CAR. In this section, other factors other than stress that affect the magnitude of the CAR are briefly described.

Gender and Age

Several investigations have shown that the CAR is greater in women than men. Results have not been completely consistent and may depend on whether measures are taken on a work or leisure day. The greater CAR in women may also be affected by the stressful demands they often encounter early in the day. Women are frequently responsible for preparing not only themselves for the day ahead but also children and for doing household chores as well. Most studies of the CAR have shown little association with age in adult populations.

Time of Waking

There has been controversy about the association between time of waking and the CAR. Several studies have shown that the CAR is greater in people who

wake up early than in those who wake later, but no association with time of waking has also been reported in a number of large-scale investigations. The issue is complicated by two factors. First, people who say they wake up late in the morning may in fact have woken earlier and have subsequently dozed. Their CAR may therefore have partly taken place prior to the reported waking time. Second, waking early may be a reflection of greater stress, worry, or work demands, which themselves influence the CAR. In one study, the greater CAR recorded in people waking before starting an early work shift was no longer significant once concomitant stress had been taken into account.

Sleep Duration and Quality

The majority of studies to date have not shown any association between sleep duration or time of going to bed and the CAR. Experiments in which healthy participants were deliberately disturbed during the night showed no change in the CAR when they later woke in the morning. The CAR is also unaffected by whether the person wakes spontaneously or with an alarm clock. On the other hand, a negative relationship between cortisol levels on waking and sleep quality has been described, and cortisol levels on waking are lower in individuals diagnosed with primary insomnia.

Smoking

Data relating smoking with the CAR are mixed, but it has recently been shown that the CAR is greater in smokers than in nonsmokers, even when they have not smoked during the early morning period.

Significance of Cortisol Awakening Response for Stress Research

The relationship between the CAR and stress-related processes is intriguing. The early studies of the CAR indicated greater responses in people under chronic stress due to work or other demands, suggesting that the CAR might be a convenient stress measure. The CAR is also greater on work than on leisure days, indicating that the stressfulness of the forthcoming day may be significant. This is illustrated in [Figure 2](#), which shows CAR results from a sample of working men and women measured on work and leisure days. It is evident that cortisol levels on waking did not differ between the two days. However, the CAR was substantially greater on work days than on weekend days. In addition, this study found a larger CAR in women than men on work days but not on weekend days.

Figure 2 Mean salivary cortisol on waking (Wake) and 30 minutes later (+30) on a work day and weekend day in men (solid lines) and women (dashed lines). Error bars are standard errors of the mean. From Kunz-Ebrecht, S. R., Kirschbaum, C., Marmot, M., & Steptoe, A. (2004). Differences in cortisol awakening response on work days and weekends in women and men from the Whitehall II cohort. *Psychoneuroendocrinology*, 29, 516–528. Used with permission.

Subsequent studies have identified several conditions in which the CAR is apparently reduced, indicating that stress-related processes may both accentuate and inhibit the CAR. [Table 1](#) summarizes the evidence to date. An enhanced CAR has consistently been found to relate to work stress and to measures such as job strain, work overload, and overcommitment to work. Both clinical depression and depressive symptoms within the nonpsychiatric population are characterized by a heightened CAR. By contrast, a diminished CAR has been recorded in people suffering from posttraumatic stress disorder and chronic fatigue and in those who have experienced early life adversity. Other types of chronic strain, such as caring for a demented relative, have been associated with a heightened CAR, while the effects of early life adversity have been variable. Research on socioeconomic status has shown inconsistent results, with elevated CAR in some studies and reduced CAR in others. The literature on burnout is also mixed, with most studies showing clinically defined burnout problems to have no effect on the CAR.

Nearly all of these effects are cross-sectional, so the causal significance of associations is unclear. However, one recent study assessed changes in financial strain over a 3-year period and demonstrated that a reduction in financial strain was accompanied by a decrease in the CAR, indicating a parallel between changes in chronic stress and the magnitude of the CAR.

The explanation for these variations among studies is not clear. They may reflect genuine differences between the patterning of the CAR in relation to different types of stressful experience. But it should be noted that several of these studies did not control rigorously for the timing of sampling. It is conceivable

Table 1 Psychosocial factors and the cortisol awakening response

<i>Factors associated with increased CAR</i>	<i>Factors associated with reduced CAR</i>	<i>Inconsistent effects</i>
Work vs. leisure days Chronic stress, work overload Job strain, overcommitment to work Depression and depressive symptoms Financial strain Loneliness Neuroticism Caregiving	Posttraumatic stress disorder Chronic fatigue	Socioeconomic status Burnout Early life adversity

that in some conditions of chronic stress, people are less reliable in the timing of measurements, leading to an apparent diminution in the CAR.

Relationship with Health Outcomes

The CAR has not been studied extensively in relation to health to date. One study divided respondents into people who did and did not report any health problem or chronic disease and showed a smaller CAR in the less healthy group. There have been a number of other interesting observations suggesting that associations may exist with physical health risk. For example, the CAR has been positively associated with waist/hip ratio in men, suggesting that it may relate to HPA dysfunction in abdominal adiposity. Another study assessed relationships with the rate of healing of a wound imposed experimentally on healthy volunteers. Wound healing was slower in people reporting high levels of subjective stress and in those with a larger CAR, indicating that stress may impair wound healing in part through disturbances in cortisol regulation. Another indication of the health relevance of the CAR is the observation that in women a greater CAR was positively associated with progression in carotid intima-media thickness and so correlated with the development of atherosclerosis. Other studies have not measured the CAR directly but, rather, assessed the cortisol level in the early morning. The values recorded in these studies may reflect the peak CAR or some time point soon afterward. Notably, the early morning cortisol level is positively associated with risk of future clinical depression in prospective studies of adolescents and adults and with cardiovascular disease risk factors.

Conclusion

The CAR has only begun to be studied in recent years in stress research, but it is already providing valuable information about the relationship among HPA function, psychosocial factors, and health risk.

Conclusion and Future Directions

Glossary

Acute coronary syndrome A general term indicating a group of clinical symptoms compatible with acute myocardial ischemia, including myocardial infarction and unstable angina pectoris.

Acute-phase response Complex series of biological reactions in response to infection, physical trauma, malignancy, or other physical challenges, involving blood clotting and inflammatory parameters. The acute-phase response can be initiated short-term (within min) and may last several days.

Antibody Protein produced by the immune system that recognizes and helps fight infections and other foreign substances in the body.

Atherosclerotic plaque

Atherosclerosis is the hardening (loss of elasticity) and narrowing of medium or large arteries. The plaque is also called an atheroma, which involves the abnormal inflammation-dependent accumulation of white blood cells, lipids, and other cells within the arterial walls.

C-reactive protein (CRP)

A marker of inflammation and the acute-phase response that can be measured in blood samples.

Cytokine

A wide range of small proteins released by cells that have specific effects on cell interactions and cell function. Cytokines include the interleukins (ILs; e.g., IL-6), lymphokines, and cell signal molecules (e.g., tumor necrosis factor and interferons). Cytokines may stimulate (pro-inflammatory) or inhibit (anti-inflammatory, e.g., IL-4) the inflammation response. Cytokines that are bound to antibodies have a stronger effect on the immune system than unbound cytokines. One of the white blood cell types involved in the immune response. The two major types of lymphocytes are T cells and B cells.

Lymphocyte

Monocyte

One of the white blood cell types that ingests microorganisms, other cells, or foreign substances. When a monocyte enters tissue, it develops into a macrophage (which surrounds, kills, and removes microorganisms).

<i>Myocardial ischemia</i>	Insufficient blood flow to part of the heart muscle, reflecting an imbalance between blood supply and cardiac demand.
<i>Pathogen</i>	An organism that causes disease in another organism, such as viruses and bacteria.
<i>Phagocytosis</i>	The process of ingesting and destroying microorganisms or other foreign substances by phagocytes. Phagocytes are cells that can ingest and destroy these foreign substances.
<i>Vital exhaustion</i>	A state characterized by unusual fatigue and loss of energy, increased irritability, and feelings of demoralization. Often precedes cardiac events. In the original conceptualization of the exhaustion construct, the term vital was included to reflect the far-reaching consequences of this condition on daily life function (similar to vital depression). We will refer to this construct as “exhaustion” in the remainder of this chapter.

C-Reactive Protein: Function and Measurement

C-reactive protein (CRP) is a member of the pentraxin protein family (molecular weight 120 kD) and a well-established inflammation marker. In the early 1930s, Tillett and Francis discovered CRP in the serum of patients with acute inflammation as a protein that reacted with the C polysaccharide of pneumococcus. Subsequent research has indicated that elevated CRP is a characteristic indicator of the acute-phase response in inflammatory disorders. The acute-phase response involves a shift in the plasma proteins released by the liver (including a decrease in albumin and an increase in CRP). The three acute-phase reactants that have been most extensively investigated are CRP, fibrinogen, and serum amyloid A (SAA), and these acute-phase proteins are well-documented inflammatory markers and mediators of atherosclerosis.

CRP is released from hepatocytes and its release is primarily stimulated by the cytokine interleukin (IL)-6. CRP mimics the function of an antibody, and is capable of complement activation. More specifically, CRP interacts with phagocytic cells at an injury site, binding to the phosphorylcholine of cell-wall polysaccharides from a wide range of bacteria and fungi. When CRP binds to a bacterium, the pathogen will become vulnerable for phagocytosis, and the immunological complement cascade will be activated. Unlike antibodies, CRP and other acute-phase reactants have no structural diversity and are not specifically released or targeted. In addition to the usual hepatic storage and release, CRP can also be stored

in the hepatic endoplasmic reticulum, and this storage diminishes during inflammation thus leading to more efficient CRP secretion. CRP may also be released from other sources, including atherosclerotic plaques, vascular tissue, lymphocytes, and monocytes. CRP is a primary marker of the acute-phase reaction because of its rapid (24–28 h) and marked response to a wide variety of inflammatory conditions. Thus, CRP is part of the innate (nonadaptive) host response to infection and other pathogens.

CRP can be measured by a variety of methods including radioimmunoassay, immunonephelometry, immunoturbidimetry, immunoluminometry, and enzyme-linked immunosorbent assay (ELISA). Methods that enable precise measurements at low CRP concentrations have been defined as high sensitivity (hs) CRP assays. High sensitivity CRP is necessary to enable assessments in apparently healthy individuals using a lower limit of approximately 0.3 mg l^{-1} , with an assay imprecision of less than 10% at a CRP concentration of less than 1.0 mg l^{-1} . Based on the biological variability of CRP, the proposed allowable analytical error has been proposed to lie between 15% and 32%. Additional standardization is still necessary for some of the available assays, but a few well-established commercial hsCRP assays are available. CRP has a long half-life (approximately 19 h), and levels are relatively stable over time, with a 5-year correlation of approximately 0.4.

Diseases with a clinically significant inflammatory component are commonly associated with CRP levels exceeding 10 mg l^{-1} . However, the elevated CRP-related risk for cardiovascular disease is documented to occur at levels between 3.0 mg l^{-1} and 10.0 mg l^{-1} . Such low-grade elevations occur in approximately one-third of the adult population, primarily in the following settings: (1) diseases with tissue dysfunction or minor damage that are not primarily inflammatory (e.g., hypertension and atrial fibrillation); (2) conditions related to metabolic or hypothalamic pituitary dysregulation (e.g., obesity, insulin resistance, sleep apnea, exhaustion, and depression); and (3) adverse health behaviors (cigarette smoking, low physical activity, and high-fat diet).

Twin studies suggest a substantial genetic component (monozygotic concordance for CRP = 0.40). Multiple genetic polymorphisms for elevated CRP levels have been documented, but none are associated with an altered CRP amino acid sequence. A wide range of relatively minor environmental challenges (e.g., secondary smoke inhalation, pollutants, and estrogen-containing substances) and inflammatory stimuli related to minor injuries (e.g., dental problems and minor respiratory infection) are known to elicit low-grade CRP responses. Depending on the nature

of the research question and study sample, these background factors need to be taken into account by statistical methods or research design.

Relationship between C-Reactive Protein and Cardiovascular Disease

Epidemiological studies have demonstrated that CRP and other acute-phase reactants predict incident and recurrent cardiovascular events. Based on population studies, clinical cut-off points for CRP have been set as: low ($<1 \text{ mg l}^{-1}$), moderate ($1\text{--}3 \text{ mg l}^{-1}$), and high ($>3 \text{ mg l}^{-1}$). CRP levels of more than 10 mg l^{-1} should lead to referral for noncardiac diagnosis because of the high likelihood of an active inflammatory disorder. Three processes are important to consider in the relationship between CRP and cardiovascular disease: (1) the role of inflammation in the onset and gradual progression of atherosclerosis; (2) immune system involvement in acute atherosclerotic plaque rupture; and (3) secondary increases in inflammatory parameters following transient myocardial ischemia and/or myocardial infarction, or damage to the vasculature.

CRP may reflect early stages of atherosclerosis characterized by cell adhesion and engulfment of lipids and T cells. CRP may promote these gradual immune system-related processes. Elevated CRP levels have long-term predictive value for adverse cardiovascular outcomes, although some evidence suggests that the predictive value is most pronounced in the first 2 years of follow-up. The predictive value of CRP is statistically independent of other inflammatory predictors of cardiovascular disease (IL-6 and tumor necrosis factor (TNF)- α), and standard cardiovascular risk factors such as cholesterol.

In advanced coronary atherosclerosis, CRP may also promote transient increases in the risk of plaque rupture by promoting plaque instability and activation. Plaque rupture is associated with activation of the blood clotting process, which is linked to inflammatory parameters. The resulting sudden obstruction of coronary blood flow may lead to sustained myocardial ischemia and infarction.

In addition to promoting gradual atherosclerosis and plaque instability, elevated CRP levels may also reflect secondary inflammatory responses in patients with cardiovascular disease. Myocardial tissue damage or transient ischemia, infection, and mechanical cell injury are all known to activate numerous biological pathways, including the cytokine and coagulation systems. CRP levels tend to peak at 48–54 h postmyocardial infarction, and the increase is proportional to the magnitude of myocardial damage as documented by troponin levels.

Recent meta-analyses have confirmed the significant association between CRP and adverse cardiovascular risk, although the magnitude of risk is lower (odds ratio 1.58, 95% confidence interval 1.48 to 1.68) than originally reported. In addition, recent Mendelian randomization studies indicate that although genetic polymorphisms give rise to elevated CRP levels, these genetic factors are not associated with increased cardiovascular risk. These findings suggest that CRP may be a marker of the underlying atherosclerotic process and/or a measure that partly reflects other risk indicators. Additional studies are needed to further establish the epidemiological and experimental evidence for the role of CRP and other inflammatory markers in adverse cardiovascular disease progression. At present, CRP is not used to directly guide clinical practice in cardiovascular medicine.

Stress-Related Psychosocial Cardiovascular Risk Factors and C-Reactive Protein

Because of the well-documented predictive value of CRP for adverse cardiovascular health outcomes, we will primarily focus on stress-related psychological factors that are known to be associated with atherosclerotic disease progression. Chronic and acute psychological factors are associated with increased risk of coronary artery disease and its clinical manifestations as acute coronary syndromes, including myocardial infarction. These psychological constructs are characterized by increased levels of perceived stress and/or exposure to potentially stressful environmental challenges. The pathophysiological mechanisms accounting for the relationship between psychological factors and coronary disease progression are likely to involve inflammatory processes. This section selectively reviews the interplay between psychological factors and CRP. A detailed review on the psychoneuroimmunological processes in cardiovascular disease has been presented by Kop and Cohen (2007: 921–943).

Prior investigations have shown that psychological risk factors for coronary disease can be classified into three broad categories, based on their duration and temporal proximity to coronary syndromes: (1) chronic factors, such as negative personality traits (e.g., hostility) and low socioeconomic status (SES); (2) episodic factors with a duration of several months up to 2 years, among which are depression and exhaustion; and (3) acute factors, including mental stress and outbursts of anger. Accumulating evidence indicates that the stage of coronary disease is a major determinant of the inflammatory mechanisms

involved in coronary disease progression and acute coronary syndromes.

Chronic Psychosocial Risk Factors and C-Reactive Protein

The chronic psychological factors discussed here are low SES and hostility, because of their well-documented relationship with coronary disease and the emerging evidence that these measures are also related to CRP. Both factors are associated with elevated levels of distress as a result of the purported increased exposure to challenging environmental circumstances and reduced resources to cope with such challenges.

SES can be defined based on a combination of education, income, job status, as well as other dimensions. Low SES is associated with elevated levels of CRP. For example, Owen et al. (2003: 286–295) documented elevated CRP levels among lower versus higher SES participants (1.18 ± 0.75 versus 0.75 ± 0.8 mg l⁻¹, $p = 0.002$) independent of sex, age, body mass, waist-to-hip ratio, smoking status, alcohol consumption, and season of the year. This finding has been replicated in larger epidemiological studies. The main potentially confounding factor in the association between SES and CRP is overweight. Nonetheless, most studies support a relationship between SES and CRP, even when statistically adjusting for body mass and other potentially confounding factors. However, because low SES is associated with a wide range of health behaviors, environmental exposures to pollutants and infectious agents, and psychological contextual factors, further studies are needed to clarify the role of SES in inflammatory factors such as CRP.

Hostility is a psychological trait characterized by a mixture of anger and disgust, and is associated with emotions such as resentment, indignation, and contempt. Hostility is predictive of long-term cardiovascular events, and this personality trait has been described as the toxic component of the type A behavior pattern. Research suggests modest (r values between 0.2 and 0.4) correlations between hostility and CRP levels. Measures of aggressive behavior are stronger predictors of CRP than general hostile attitudes. The mechanisms by which trait hostility, and particularly aggression, result in elevated inflammatory factors may involve stress-activated neurohormonal and autonomic nervous system pathways. Noradrenergic stimulation may increase gene expression for various inflammatory cytokines including IL-6, which may result in CRP release. Frequent responses to aversive interpersonal interactions may result in heightened noradrenergic drive in hostile individuals and thus result in increased production of pro-inflammatory cytokines and CRP.

Episodic Factors and C-Reactive Protein: Exhaustion and Depression

Prolonged emotional challenges may result in general distress, exhaustion, and depression. These stress-related conditions wax and wane with the intensity of the environmental challenges and the success of an individual's coping strategies. The predictive value of these conditions for cardiovascular events is strongest in the first 2 years after assessment. Because of the transient nature of these conditions and their stronger predictive value for adverse events within 2 years following assessment, these factors are referred to as episodic psychological risk factors.

Episodes of prolonged distress have been associated with markers of immunosuppression. The psychoneuroimmunology literature generally categorizes the immunosuppressive correlates of distress-related conditions along with the long-term immunological consequences of depressive disorders and other conditions characterized by negative affect (e.g., bereavement, separation, and daily hassles). Based on the Cardiovascular Health Study, our group has documented significantly elevated CRP levels among exhausted men (6.82 ± 2.10 mg l⁻¹) versus nonexhausted men (3.05 ± 0.16 mg l⁻¹; $p = 0.007$) aged over 65 years. The association for women was less strong, but still statistically significant when adjusting for co-variables including age, gender, race, diabetes mellitus, smoking status, and systolic blood pressure. Elevated CRP levels in depression, exhaustion, and other markers of prolonged distress have been consistently reported in the literature, with only a few exceptions (3/30 reviewed articles).

The mechanisms accounting for the associations between exhaustion and depression with CRP include biological pathways involving the central and autonomic nervous systems, and adverse health behaviors (e.g., overweight status and smoking). Prolonged distress commonly results in norepinephrine released from the locus coeruleus as well as hypothalamic corticotropin-releasing hormone (CRH), which are the main effectors of what Selye has described as the general adaptation response. The most common finding in depression, especially melancholia, involves activation of the CRH system and hence elevated cortisol levels. The clinical nature of depression (i.e., melancholic depression versus atypical depression and exhaustion) may influence the association between depressive symptoms and immune system parameters. CRH is elevated in typical depression, and acts as the main regulatory hormone in the acute-stress response, resulting in the release of pro-inflammatory cytokines, as well as a wide range of other immune system responses. These effects may be less strong or even reversed in atypical depression and exhaustion.

The autonomic nervous system also plays an important role in the acute-phase reaction, and parasympathetic outflow inhibits macrophage activation via the cholinergic anti-inflammatory pathway. Exhaustion and depression are associated with decreased parasympathetic nervous system activity, which may thus contribute to elevations in pro-inflammatory cytokines and elevated CRP.

The neuroimmunological responses to prolonged distress generally occur in the context of health behavior-mediated physical changes, particularly being overweight, affecting multiple metabolic processes. Thus, an overall imbalance of normal homeostatic function may be characteristic of episodic risk factors, resulting in prolonged CRP elevations.

Acute Psychological Factors and C-Reactive Protein

Acute psychological factors relevant to cardiovascular disease involve responses to acute mental or emotional challenges, such as outbursts of anger. These acute psychological factors can act as triggers of myocardial infarction by inducing cardiac ischemia and promoting plaque rupture and thrombus formation in advanced stages of coronary artery disease. There is increasing interest in the role of acute stress-induced inflammatory responses in relation to cardiovascular disease risk.

Some evidence suggests that acute mental challenge tasks induce elevations in CRP in individuals with inflammation-related conditions. However, in healthy individuals the results have been largely negative. One study examined CRP 45 min and 2 h postmental stress in healthy individuals, without significant CRP elevations. The optimal timing of CRP reactivity is an issue of current debate. Studies have demonstrated an immediate response in patients with cardiac problems and individuals with rheumatic arthritis (<5 min poststress).

A few methodological issues are relevant to the acute CRP response. Acute psychological distress elicits increases in arterial blood pressure and changes in blood rheology, including decreases in plasma volume and increases in blood viscosity. CRP is a relatively small molecule, but when plasma volume decreases in response to mental challenge, CRP does not readily pass into the interstitial space because of its molecular structure. Therefore, studies examining the acute CRP response need to adjust for changes in plasma volume. CRP levels at baseline are also highly correlated with levels obtained during mental stress (r values of >0.85), which results in statistical significance of very small absolute changes from baseline. Of note is that IL-6 responses tend to be unrelated to CRP responses, which suggests that mechanisms

other than hepatic release may play a role in the acute CRP response. These may include endothelial cells and other tissues, and the local release could possibly be mediated by circulating neurohormones. However, acute CRP responses may not be as important when compared with other acute responses of the immune system relevant to cardiovascular disease (e.g., IL-6, shift in lymphocyte distribution towards increased CD8+ and decreased CD4+). The timing of IL-6 should theoretically precede hepatic CRP release, and current data do not support such a pathway. Storage of biologically active signals can cause an immediate physiological effect, but the translation from messenger ribonucleic acid (mRNA) to protein takes several hours. Acute increases in circulating CRP are therefore not likely to reflect production of newly synthesized protein by tissues such as vascular endothelial cells or adherent leukocytes.

Conclusion and Future Directions

CRP is a critical component of the innate immune system, providing early defense against infectious agents and other pathogens. Substantial individual differences have been observed in CRP levels in the range below clinical inflammation (i.e., CRP levels <10 mg l^{-1}). Psychological factors are associated with elevated CRP levels, and distress-related inflammatory processes may therefore partially account for the relationship between psychosocial factors and adverse cardiovascular health outcomes. Evidence for elevated CRP levels is strongest for episodic risk factors such as depression and exhaustion. These conditions reflect the consequences of prolonged psychological distress, and elevated CRP levels in these conditions have a plausible biobehavioral explanation. Evidence for chronic psychosocial factors is also consistent, with the strongest support for low SES as predictor of elevated CRP. Acute CRP responses have been documented in patients with rheumatic arthritis and coronary disease, but the acute effects are small and probably do not reflect an increase in CRP secretion but rather a redistribution of CRP.

Further studies are needed to document the relative importance of catecholamines and hypothalamic pituitary adrenal axis hormones in elevated CRP levels. These studies need to be conducted in the context of important behavioral concomitants of inflammation, particularly assessments of adipose tissue because metabolic imbalance may be a common explanatory factor. In addition, prolonged stress may lead to increased allostatic load which may further promote the cascade of distress and elevated inflammatory markers.

Many of the psychological factors mentioned above are interrelated, which partially results from

the currently available measurement tools but may also reflect a general stress-related psychological factor. Such a general prolonged distress factor could account for increased levels of pro-inflammatory markers. More research is needed to identify potentially common environmental and/or genetic factors for vulnerability for stress-related psychological traits and high levels of inflammatory parameters.

Minor CRP elevations are associated with a diverse range of conditions. Current research suggests that the stimulus for CRP production involves a mild degree of tissue stress or injury, suggesting the presence of challenged cells, rather than a subsequent inflammatory response to these cellular challenges. Nonetheless, CRP has potentially pragmatic utility for cardiovascular-risk stratification, and further improvements in the assessment of inflammatory processes will contribute to a better understanding of the biopsychosocial factors involved in cardiovascular and other inflammation-related disorders.

Victimization

Psychological and Physical Health Consequences

Responses to Specific Crimes

Support and Treatment Services

Glossary

Acute stress disorder (ASD)

A disorder that may occur in the immediate aftermath of severe trauma. The diagnostic features include dissociation in the form of numbing, reduction in awareness, derealization, depersonalization, and dissociative amnesia. There is anxiety and increased arousal, which often accompanies reexperiencing of the trauma. As a consequence there is avoidance of reminders of the trauma and impairment in social or occupational functioning. The diagnosis of ASD requires three dissociative symptoms but only one symptom from the intrusion, avoidance, and arousal categories.

Posttraumatic stress disorder (PTSD)

Occurs following exposure to a traumatic event in which the person witnessed or was confronted with an event that involved actual or threatened death or serious injury to themselves or others and where their response involved intense fear, helplessness, or horror. It is characterized by persistent reexperiencing in the form of recurrent, intrusive thoughts or images and/or distressing dreams or flashbacks. There may be intense distress or arousal when confronted with reminders of the event. As a consequence there may be persistent avoidance of things associated with the trauma and numbing of general responsiveness. There may also be sleep disturbance, irritability or outbursts of anger, difficulty in concentration, hypervigilance, and exaggerated startle response. The symptoms result in significant impairment of social, occupational, or other important areas of functioning and need to last longer than 1 month for a diagnosis to be made.

Victimization

It is difficult to estimate the extent of criminal victimization in part because most victims of crime do not report the event to the police, resulting in an underrepresentation within the criminal statistics compiled from police data. Most crime differentially targets and damages victims who are poor, marginalized, and disempowered within society; individuals are usually targeted because of what they represent rather than because of who they are. Examples of this can include racially motivated attacks or sexual assaults. Within the United Kingdom the recent British Crime Survey of 1998 pointed to an 83% increase in crime since 1981, with the largest increase being in violent crime. Women are more likely to be at risk for sexual or domestic violence, whereas men are more likely to report physical violence from strangers.

Being the target of a crime may result in the individual feeling that he or she is a victim. Ochberg reported that victims feel diminished, pushed down, exploited, and invaded. There is a feeling of stigmatization and of being isolated by the experience, with a shattering of basic assumptions about the predictable orderly nature of the world where bad things are perceived as only happening to people who deserve it. Individuals lose their sense of autonomy, and their belief in being able to control their own lives is shattered, with a consequent increase in feelings of vulnerability. This is often associated with a belief that others do not understand unless they have experienced being a victim themselves. This feeling may be reinforced by the critical response they experience from friends or family when their recovery is not sufficiently rapid.

There may also be a considerable amount of self-blame, which may take one of two forms: behavioral or characterological. Behavioral self-blame is concerned with aspects of behavior that, if changed, could reduce the possibility of reoccurrence, whereas characterological self-blame implies that the victimization is attributable to the sort of person that the victim is. Clearly, behavioral self-blame, since it implies the possibility of increased control over events, is more healthy than characterological blame.

Psychological and Physical Health Consequences

Victims of violence may experience a sense of detachment or depersonalization at the time of the attack.

While this may be a protective mechanism in the immediate aftermath of an attack, it may well hinder subsequent recovery, and recent evidence suggests that it may predict the subsequent development of posttraumatic stress disorder (PTSD). While dissociation is not a feature of PTSD, it is one of the major features of the diagnosis of acute stress disorder (ASD). Recent research has found that a diagnosis of ASD 1 month after experiencing a violent crime predicted the development of PTSD in 83% of cases at 6-month follow-up.

Many of the psychological consequences fit within the PTSD framework, with as many as 27% of all female crime victims meeting the criteria for diagnosis. Assaultive violence is more damaging than other types of crime, with higher rates of PTSD relating to increased perception of threat to life and extent of physical injury. In addition to PTSD, depression, anxiety, and substance abuse are common consequences of criminal victimization.

As well as the direct effects of the crime in terms of physical damage, victims are more likely to have poorer physical health and report increased drug and cigarette and alcohol consumption, health-care neglect, risky sexual behavior, and eating disorders.

Responses to Specific Crimes

Rape and Sexual Assault

Definitions as to what constitutes rape vary across countries. Within the United Kingdom the definition has recently been extended to include nonconsensual anal intercourse as well as vaginal intercourse. This change allows sexual attacks on men to be treated for the first time in law as rape, although it has to be acknowledged that the majority of victims of rape are women. Most sexual offences are unreported, and the rate of successful prosecution is low. Rape trauma syndrome was described by Burgess and Holstrom in 1974, but is now regarded as a variant of PTSD. Being the victim of a completed rape, being injured, and the extent of the perception of threat to life are predictive of increased rates of subsequent mental health problems in the longer term, as are prior victimization, previous psychological problems, and the lack of available social support. A third of women who report rape develop long-term psychological and social problems. A similar pattern was described in male victims of sexual assault by Mezey and King.

Stalking

Stalking has as yet been relatively poorly researched. Pathe and Mullen described severe social disruption and psychological distress with high levels of anxiety,

persistent intrusive recollections and flashbacks, and suicidal thoughts. There are profound economic and social consequences of stalking, as victims often feel compelled to leave their employment or change their address. Over a third of victims in the Pathe and Mullen study met the criteria for PTSD.

Domestic Violence

Domestic violence, like sexual violence, is primarily but not exclusively directed against women. It is defined as an act carried out with intent to physically injure another person, usually an intimate partner. Recent surveys in the United Kingdom have suggested a lifetime prevalence of domestic violence of 1 in 4 women and an annual prevalence of 1 in 9 women. Battered woman syndrome, first described in the 1970s, contains within it many of the features of PTSD and describes the emotional, cognitive, and behavioral consequences. It is associated with apparent learned helplessness, whereby the victims of domestic violence appear to be unable to extricate themselves from abusive relationships. Rather than being helplessness, this unwillingness to leave an abusive partner may in fact be a rational appraisal of the danger involved in freeing themselves from an abusive partner. The degree of risk is seen in terms of the possibility that the domestic violence may end up causing severe physical injury and can progress to homicide. The consequences of domestic violence include depression, anxiety, suicidal behavior, substance abuse, and somatization. It is a frequent cause of divorce and homelessness and may be associated with child abuse.

Workplace Violence

Workplace assaults have increased in frequency and severity in recent years and are associated with increased job stress, reduced job satisfaction, and the likelihood of carrying weapons to work. Males are most likely to be involved in fatal workplace assaults, while women are more likely to be involved in nonfatal assaults. Health-care workers are particularly affected, with the rates for health- and social-care workers being 10 times those in non-health-care industries. Around a quarter of nurses and doctors report physical assaults in the course of their work.

Murder

Murder, unlike death by natural causes, disproportionately affects the young, leaving relatives, particularly parents, feeling as if their future has been taken from them. Relatives of murder victims often feel stigmatized and isolated, with a sense of shame and betrayal, which results in their being unable to communicate their distress or make emotional

contact with others. The impact of traumatic bereavement may include physical symptoms, cognitive impairment, depression, and phobic avoidance as well as impaired work and social functioning. There is often a feeling of being let down by the criminal justice system, which compounds the sense of loss.

Robbery and Burglary

The effects of burglary may include PTSD but are generally less severe and long lasting. They may, however, include depression and anxiety and a sense of violation, which may be the most distressing and difficult aspect to resolve. Robbery, unlike burglary, involves direct contact with the perpetrator as well as a degree of threat to life and is therefore more likely to result in PTSD. Predictors of good recovery include a lower perception of threat to life, having had a preexisting view of the world as meaningful and orderly, and a rapid reduction of symptoms within the first month, whereas a depressive and avoidant coping style, fear of future violence, and increased somatic symptoms over time are associated with a poorer outcome.

Mass Shootings and Terrorist Crimes

While terrorist crimes are relatively infrequent, their social impact is much more widespread, inducing a climate of fear and uncertainty. For individuals caught up in terrorist attacks, the degree of threat to life and the extent of physical injury sustained during the attack are the best predictors of psychological problems, particularly PTSD, both in the immediate and the longer term. In the context of Northern Ireland a number of studies have found significant numbers of those with direct experience of terrorist incidents to be suffering from PTSD. This is in contrast to research on the impact of terrorist violence on the general population, which has been unable to detect a relationship between terrorist violence and resultant mental health problems in the population at large.

Studies that have looked at the impact of shootings tend by their very nature to be small scale but have found significant levels of distress and high rates of PTSD and other psychiatric disorders, with 33% or more being diagnosed as suffering from ASD in the immediate aftermath and this diagnosis being predictive of PTSD symptoms at follow-up several months later. Similarly, being held hostage has been related to high levels of subsequent distress both in victims and in their families. Victims of hostage taking may experience strong attachment and paradoxical gratitude toward the captors, with positive emotions including compassion and romantic love occurring. This may

be expressed as profound gratitude for being allowed to live and has become referred to as Stockholm syndrome.

Support and Treatment Services

There are few culturally accepted rituals used to support victims of crime. This means that a major strategy in treatment and support services involves normalizing the process. In the first instance this may be best achieved by victim support schemes, which offer practical assistance such as accompanying people to court hearings, guiding them through the process of applying for compensation, and dealing with the complexities of the criminal justice system. They also offer emotional support and the opportunity to ventilate emotions following a crime. Referrals to schemes are often automatically made by the police but may also be made from mental health professionals or may be requested by victims themselves. Despite the high prevalence of PTSD in victims of crime who participate in the criminal justice system, there is still ample evidence that they do not have adequate access to mental health services. This occurs despite awareness that victims of serious crimes and the families of murder victims may develop psychiatric illnesses that require referral to mental health services for specialist treatment.

There has been an assumption that early intervention is more successful. There are few controlled studies of the impact of early intervention. Those that do exist seem to be evenly divided between three categories, i.e., bringing about improvement, having no impact, and resulting in deterioration, so as yet it is not possible to assume that early intervention is either effective or at least harmless. Research on victims of serious crimes such as rape suggests that in the immediate aftermath the majority of victims would meet the diagnostic criteria for PTSD but that by 4–5 months this decreases substantially to less than half. If recovery does not occur during this time then subsequent improvements may be slow, resulting in chronic problems. The fact that the majority of victims may recover spontaneously should not diminish the need for provision of adequate services for the significant minority who do not improve.

The effects of criminal victimization may be severe and incapacitating and may have long-term economic and social consequences. Victims of crime are rarely vocal on their own behalf, and as a consequence their needs may be unrecognized, both by the population at large and by health professionals in particular.

Critical Incident Needs Assessment Teams
Conclusion

Glossary

Crisis The critical turning point of a situation or event; can be an individual crisis or a population-level/community crisis.

Psychological first aid A group of evidence-informed interventions that can be helpful in the immediate aftermath of a crisis or traumatic event.

Resiliency The dynamic process of healthy response and coping in the face of adversity.

Risk communication Scientifically based method for communicating effectively under high-stress conditions.

Terrorism Intentional acts of human malevolence with the primary goal of causing terror; implemented by those who wish to coerce societies by inducing fear, shock, horror, and revulsion, often with ideological, religious, and political agendas.

A crisis is defined as a critical turning point of a situation or event. Crises can occur at the individual or community levels and affect one person or an entire population. Typically crises arise for after severely stressful events. For example, stressful events include traumatic events (i.e., car accidents) affecting individuals and large-scale disasters (i.e., hurricane, earthquake, or terrorism) that have profound effects on communities and nations. Crises are of variable

duration; they can be short-lived or persist for months and years. Over time, crises attenuate, resolve, or worsen, depending on the nature of the inciting event and its management. During severe crises, affected individuals often experience a period of stress, uncertainty, and anxiety and are concerned about their own safety or the safety of others. Each crisis often is followed by a series of crises (e.g., secondary crises such as loss of job, illness, or dislocation) that further stress the individual, group, and community.

Impact of Crises

Crises evoke a variety of reactions. Resilience and recovery are the rule, and most individuals do not develop chronic problems. For some, however, there are adverse psychological and behavioral responses. In crises precipitated by traumatic events such as disaster or terrorism, many people may experience sleeping difficulties; feel worried, sad, and anxious; increase alcohol and tobacco use; and change their regular behavior (e.g., alter their usual means of travel). Challenges to their faith and spiritual beliefs may also occur (Figure 1).

Many acute negative behavioral and emotional responses remit over time and do not require formal treatment. This tendency toward recovery is often credited to resiliency, a dynamic process of health recovery and coping in the face of adversity. Optimism, intelligence, humor, creativity, and active coping are related to resilience and positive outcomes after crises. Through active coping, individuals accept the impact of traumatic events and implement attainable, concrete measures to improve things.

Although many people experience distress after a crisis, some experience more persistent psychological

sequelae, such as anxiety, insomnia, increased smoking, increased alcohol consumption, and bereavement. This group may benefit from supportive psychological interventions, including psychological first aid and brief pharmacological interventions for sleep or anxiety. A still smaller group will develop psychiatric illness, including anxiety disorders (acute stress disorder, ASD; and posttraumatic stress disorder, PTSD), major depressive disorder, and substance use disorders. Such individuals require more formal (and perhaps more prolonged) interventions, including psychiatric treatment.

Individual responses to a crisis, which can include a traumatic event, a severe life stressor, or disaster, depend on a number of factors. Responses are influenced by proximity and involvement with the precipitating event. For a traumatic event, this means the severity of the trauma (e.g., degree of life threat). Responses are affected by psychological factors as well as interpersonal, family, and community stressors. In addition, research suggests social contexts, past experiences, future expectations, and genetic makeup interact with the characteristics of traumatic event to produce an individual's psychological response. Other identified risk factors that appear to increase the severity and/or duration of negative response include gender (e.g., women are more likely than men to develop acute PTSD), low level of social support, previous psychiatric illness, previous history of trauma, and ongoing negative life events after the trauma.

Groups and communities are also affected by crises, including the closing of a major community employer, the death of a beloved leader, and disasters. A community's response to a disaster often runs a predictable, but at times paradoxical, course. Communities temporarily coalesce immediately after a traumatic event. This is also known as the honeymoon period. During this time, individual heroics, a sense of working for a common cause, altruism, and "we will survive" attitude pervade the community. As time evolves, however, this optimism can change to disillusionment and often exposes the social fault lines of conflict, suspicion, and differential resources that are present along racial, ethnic, economic, and religious divides.

Community (as well as individual) responses to disasters are more pronounced when the trauma is intentional or the disaster humanmade. A relevant, modern-day example is terrorism. Here, acts of human malevolence are implemented with one primary goal – to cause terror. Terrorist acts are implemented by those who wish to coerce societies by inducing fear, shock, horror, and revulsion, often with ideological, religious, and political agendas.

Figure 1 Psychological consequences of disasters, terrorism, and crises. PTSD, posttraumatic stress disorder. Adapted from Institute of Medicine (2003), *Preparing for the psychological consequences of terrorism: a public health strategy*, Washington, DC: National Academies Press.

Although acts of terrorism may lead to death, injury, property damage, and the evacuation and displacement of communities, the main aim is to challenge a society's sense of well-being, cohesion, and security. The severity and length of the crisis may increase if chemical, biological, nuclear, radioactive, or high-yield explosives (CBNRE) agents are used because these agents are particularly effective in causing terror. The infectiousness of biological agents, the persistence of chemical weapons, and the delayed effects of radioactive agents, in particular, perpetuate fear and induce terror.

A variety of interventions are used to attenuate the course of and speed the recovery from a crisis. Although all such interventions have been developed to be helpful for those affected, it should be noted that some interventions are more helpful than others, and there are some interventions that may be harmful. The effectiveness of any crisis intervention depends on a number of factors, including timing and availability. Some interventions, for example, must take place immediately after the onset of a crisis (such as ensuring safety and basic needs). Others interventions take place weeks to months later, as the focus, concerns, and emphasis shift over the evolution of the crisis. Beyond life-saving actions, subsequent interventions can help mitigate the risk of or the degree of problems for those who survive. The principles of crisis intervention for large-scale disasters are discussed in the following sections.

Planning for Crisis

Large-scale community crises, such as a disaster, illustrate the range of principles important to crisis intervention. Although the term crisis intervention may seem to refer to actions taken only after disasters occur, steps that can be taken prior to the occurrence of such events should also be part of public health planning for crisis intervention. For example, an inventory of available resources (including personnel, material, and monetary) can be developed before a crisis. Important government and community leaders and spokespeople can be identified, at-risk populations accounted for (Table 1), and gaps in the current support and response systems can be examined. Educating leaders in the principles of risk communication may provide them with skills to assist in calming people, dispelling rumors, and maintaining the leaders' credibility after a disaster. Similarly, pre-event education of the populace about personal preparedness is also an important part of crisis intervention. Preparedness plans include forming a communication plan with loved ones, establishing and mapping out

Table 1 Populations at risk for psychological problems after disaster

Previous exposure to trauma, particularly childhood
Direct exposure to the trauma/event (to include physically injured)
Those with premorbid psychiatric illness
Those experiencing acute losses
First responders (police, firefighters, emergency medical technicians)
Female gender
Those with minimal social support
Body handlers
Children
Elderly
Physically disabled
Those with negative life experiences after the trauma

evacuation routes, having extra medical supplies, developing care plans for pets, and having extra necessities on hand in the event of an evacuation (e.g., at least a half tank of gas in the car at all times, extra batteries, plenty of bottled water, and nonperishable food items).

Interventions During and After the Crisis

In the immediate aftermath of a large-scale crisis such as a disaster, the most important interventions focus on medical emergencies and life-threatening emergencies. Although it is not known (and it is difficult to predict) how the public will react to a large-scale disaster such as the Madrid or London bombings or the anthrax attacks in the United States, previous responses to disasters have shown generally effective and collective action. Depending on the cause of the traumatic event, there may be a large number of people seeking medical care. These numbers will very likely increase and overwhelm medical capacity if CBRNE agents are involved. Biological, chemical, and radioactive agents (due to their invisible, odorless nature) tend to induce a great number of people who are not at actual risk of exposure to believe they might have been exposed.

Crisis intervention, from a mental health standpoint, includes working with medical personnel to perform initial triage. Those who are not reassured easily may benefit from a brief stay in an area that has been set aside, preferably close to the emergency room. In this way, acutely distressed patients have the opportunity to reconstitute while still being monitored. In dealing with this population, terms such as the worried well and psychological casualties should be avoided. These terms are pejorative and convey a message that it's all in their head. Recognizing that these individuals are experiencing distress and require

caring responses can produce calm. The creation of a voluntary registry for individuals who are seen in the emergency room is not only a good public health intervention but can be therapeutic as well.

In addition to attending to the immediate medical needs, early crisis intervention addresses the basic needs of the survivors and includes safety from further harm as well as providing food, water, and shelter. As these needs are met, psychological first aid (PFA) can be employed. PFA is an evidenced-informed intervention that can be helpful in the immediate aftermath (hours to days) of an event (Table 2). The principles of PFA include establishing a sense of safety, facilitating social connectedness, fostering optimism, decreasing arousal, and restoring a sense of self-efficacy (e.g., the ability to take positive action). PFA can be thought of as flexible, supportive, and unlikely to cause harm; its main objectives are to limit distress, emphasize healthy behavior and activities, and minimize negative health behaviors. Although education and training in the PFA principles are required, the application of PFA can be accomplished by laypeople and does not require specific mental health expertise.

Brief simple conversations and informal on-site talks with survivors and responders can be of great assistance. This early crisis intervention avoids mental health labeling, offers support, education, and problem-solving techniques. Later interventions include cognitive-behavioral therapy (CBT). CBT has demonstrated efficacy in the prevention of PTSD in those with acute stress disorder after trauma exposure. One well-publicized disaster intervention known as psychological debriefing has not been shown to prevent PTSD and may be harmful in certain settings. Supportive and educational groups should be conducted by experienced and well-trained personnel; should be accompanied by clear objectives, evaluation, and referral procedures; and should never be mandatory.

Crisis intervention also includes good risk communication, a scientifically based method for

communicating effectively under high-stress conditions. The development of an effective risk communication strategy (as part of preevent intervention) is of vital importance in enabling leaders to inform and direct diverse populations. Individuals in the community look to their leaders for information, inspiration, a sense of control, optimism, and help during their period of grief. A major goal of the leaders should be to enlist the public as a partner. Information must be delivered frequently by credible and consistent sources. Messages should avoid speculation, never mix facts with reassurance, recommend specific steps people may take to protect themselves, and inform people when the next messages will be delivered. Good risk communication helps reduce negative psychological responses, encourage responsible safety behaviors, build trust, and minimize rumors and misinformation.

Critical Incident Needs Assessment Teams

Community crisis intervention that incorporates these principles in population health strategies must allocate and target resources at the individual, group, and community levels. Deploying critical incident needs assessment teams (CINATs) can be a helpful initial response to community disasters and crises. Such teams initiate planning, obtain on-site assessment, begin leadership consultation, and provide initial on-site guidance and support. CINATs thus are mental health-public health disaster response teams. CINATs are multidisciplinary and combine a public health approach and mental health knowledge to identify and respond to crisis. Teams initially quantify and identify needs in order to appropriately direct intervention and outreach resources.

CINATs recognize that interventions and responses are integrative, depend on a collaborative effort, and must use the community's inherent resiliency to help promote recovery. Teams can work effectively in responding to crises at workplaces (e.g., a shooting at a school or an airport after a crash). They target the individual and group levels that share a common task, mission, culture, structure, and/or physical proximity.

To be effective, CINATs require familiarity with the community or group they are deploying to assist. They may already be familiar with the given community or have received education and training about the community structure, culture, and leadership. These multidisciplinary groups include psychiatrists, psychologists, social workers, and mental health technicians. Additional individuals with particular areas of expertise, such as clergy and individuals responsible

Table 2 Principles of psychological first aid

Establish safety; identify safe areas and behaviors
Maximize individuals' ability to care for self and family and provide measures that allow individuals and families to be successful in their efforts
Teach calming skills and maintenance of natural body rhythms (e.g., nutrition, sleep, rest, exercise)
Maximize and facilitate connectedness to family and other social supports to the extent possible
Foster hope and optimism while not denying risk

Table 3 Grief leadership actions after disasters^a

Performs public announcements, appearances, and briefings
Presents calm demeanor
Organizes memorial services
Attends funerals, grieves
Endorses the various assistance programs
Attempts to describe loss in positive terms (acknowledging sacrifice and contributions)
Presents future goals and objectives

^aAdapted from Wright K. M. and Bartone P. T. (1994), Community responses to disaster: the Gander plane crash. In: Ursano, R. J., McCaughey, & Fullerton C. S. (eds.) *Individual and community responses to trauma and disaster*, pp. 267–284, Cambridge, UK: Cambridge University Press.

for security, communications, management, employee assistance, and human resources may be added.

In the aftermath of a community crisis, these pre-identified teams deploy to evaluate mental and behavioral health needs, identify high-risk groups, assist leadership function, and identify needed resources. CINATs avoid pathologizing appropriate responses to trauma and loss, and they identify those at greatest risk for subsequent problems. CINATs are a first population-level intervention. Subsequent care is arranged and distributed based on this epidemiological assessment. These teams also provide early support, education, PFA, and teaching about grief leadership (Table 3). CINATs may identify the need for additional supports including family support centers complete with legal assistance, casualty affairs assistance, Red Cross, and adult and child mental health counseling.

Conclusion

Crises affect both individuals and communities. Disasters are a severe form of crisis. Interventions can foster resiliency and mitigate adverse responses and health risk behaviors for individual and community crises. Interventions include PFA for individuals, CINAT for community assessment and early intervention, and traditional health care for those more severely affected. With appropriate planning, proper implementation, considerate timing, and coordinated execution, an effective and efficient response can foster resiliency, limit impairment, and speed recovery.

Crisis intervention is not one size fits all approach and requires thoughtful consideration and planning. Crisis interventions must always be acceptable to the survivors and their culture. Even the most well-thought-out plans cannot account for every possibility. Leaders and helpers require flexibility in their

approach and must meet disaster victims where they are – both literally and figuratively. Finally, those providing crisis intervention require support. They often do so with altruistic and noble intentions, and it is imperative that they take care of themselves as well as those they attempt to help.

Critical Thermal Limits of Ambient Temperature
Critical Thermal Limits of Body Temperature

Glossary

<i>Homeotherm</i>	The pattern of temperature regulation in a species in which the cyclic variation in core temperature is maintained within arbitrarily defined limits ($\pm 2^\circ\text{C}$) despite much larger variations in ambient temperature.
<i>Thermal balance</i>	Equality between heat gain and heat loss to maintain body temperature at a constant level.
<i>Thermoeffector</i>	An organ and its function that affects heat balance in a controlled manner as a part of the process of temperature regulation.

Critical thermal limits can be defined for homeotherms (1) as the highest and lowest ambient temperatures at which the rate of evaporative heat loss or the rate of metabolic heat production must be increased to maintain thermal balance, (2) as the highest and lowest ambient temperatures at which the capacity for temperature regulation is exceeded and core temperature changes (the development of hyper- or hypothermia), or (3) as the lethal highest and lowest body core temperatures.

Critical Thermal Limits of Ambient Temperature

Critical Thermal Limits for Activation of Thermoeffectors

Within a certain range of ambient temperature, heat production is at its minimum. This temperature range is called thermoneutral zone or metabolically indifferent zone. Within the thermoneutral zone, there are no regulatory changes in metabolic heat production or evaporative heat loss. The absolute highest or lowest limits, as well as the width of the thermoneutral zone, depend on body size, heat insulation, the heat transfer coefficient of the surrounding medium (e.g., water, wind), and the status of acclimation. For example, the metabolism of the arctic white fox does not start to rise until the ambient temperature decreases below -40°C , whereas a nude human starts to increase heat production at external air temperatures of 27°C and lower. The zones of thermal neutrality for a number of representative homeothermic species are shown in [Figure 1](#).

Critical Thermal Limits for the Thermoregulatory Capacity

The so-defined highest critical thermal limit depends on the capacity of the thermoeffector (i.e., the capacity to dissipate heat by evaporation of water) and on body size. At a low relative humidity of approximately 15%, the average external heat tolerance limits are 60°C for humans, 56°C for dogs and cats, 42°C for rabbits, 39°C for rats, and 37°C for mice. As long as a sufficient amount of water is supplied, these species can tolerate the listed ambient temperatures for longer periods. The limit of cold tolerance primarily depends on the effectiveness of the heat insulation that covers the body. Thus, it is not surprising that naked humans,

Figure 1 Thermoneutral zones (metabolically indifferent zones) of some homeothermic species. The left end of each bar indicates the ambient temperature at which the minimal resting metabolic heat production starts to increase. The right end of each bar indicates the ambient temperature at which mechanisms of heat dissipation (sweating, panting) are activated. Modified from Precht, H., Christophersen, J., Hensel, H. and Larcher, W. (1973). *Temperature and life*. Berlin: Springer-Verlag, Used with permission.

without an insulating hair coat, possess only moderate cold resistance. Unclothed humans can maintain a constant body core temperature for approximately 1 h at an ambient temperature of -1°C , whereas rats can withstand an external temperature of -25°C and the arctic white fox a temperature of -80°C for 1 h without any decrease in core temperature. In contrast to the quality of insulation, the extent of possible changes in the metabolic rate is a less important factor for the external limit of cold tolerance. In homeothermic animals whose insulation is poorer, the cold-induced increase of metabolic heat production is stronger than in well-insulated animals and starts at higher ambient temperatures.

Critical Thermal Limits of Body Temperature

This kind of thermal range refers only to the highest and lowest body core temperatures that a given species can survive. With regard to the lethal body temperature limits, the time factor (i.e., the duration of extreme body temperatures) is critically important.

Upper Limit of Body Temperature

The highest lethal body temperatures of homeotherms fall within quite a narrow range, which is only a few degrees above the normal body core temperature. The upper lethal body temperatures of some species are summarized in Table 1. It should be noted that a number of organs or even parts of the body can be warmed to temperatures higher than the general lethal body temperature. Due to this fact, experimentally

Table 1 Highest lethal body temperature in some representative homeothermic species^a

Species	Lethal temperature ($^{\circ}\text{C}$)	Remarks
Mouse	43.3	
Rat	42.5	50% lethal
Guinea pig	42.8	50% lethal
Rabbit	43.4	50% lethal
Cat	43.4	50% lethal
Dog	41.7	50% lethal
Human	45.0	Short-term survival
	43.0	Usually fatal

^aData compiled from Precht, H., Christophersen, J., Hensel, H. and Larcher, W. (1973). *Temperature and life*. Berlin: Springer-Verlag, Used with permission.

Table 2 Lowest lethal temperatures in some representative homeothermic species^a

Species	Lethal temperature ($^{\circ}\text{C}$)	Remarks
Rat	13	Cardiac arrest
Rat	-3	Supercooled, artificial hypothermia, revival
Guinea pig	17-21	
Cat	14-16	
Dog	15-18	
	0-2	Extracorporeal circulation revival
Human	24-26	Average accidental hypothermia
	18	Lowest accidental hypothermia, revival
	9	Artificial hypothermia, 45 min cardiac arrest, revival

^aSome cases of revival after artificial hypothermia and rewarming are included. Data compiled from Precht, H., Christophersen, J., Hensel, H. and Larcher, W. (1973). *Temperature and life*. Berlin: Springer-Verlag, Used with permission.

induced local hyperthermia is used in oncotherapy with the aim of destroying tumor cells.

Lower Limit of Body Temperature

The lowest lethal body temperatures for homeotherms are usually between 15 and 20°C . By the use of special techniques for cooling and rewarming, it is possible to lower the body temperature of a subject (human or animal) far below the usually lethal levels and to revive him or her unharmed. The lower lethal body temperatures of some species, including a few cases of revival under extreme conditions, are summarized in Table 2.

Small and big phenotypes

Small and big phenotypes are well separated in most organisms. Smalls are optimized for low resources (crowded conditions), while bigs are optimized for high resources. These phenotypes are epigenetically inheritable, and their conversion often requires three generations.

Conclusions

Glossary

Amyloidosis

A severe pathological change of various organs and tissues during which aggregated amyloid fibers develop and induce the destruction of affected cells.

Channeling

Interaction of enzymes catalyzing consecutive enzyme reactions in which the product of the first reaction becomes the substrate of the second enzyme by a direct molecular transfer largely avoiding free diffusion.

Hypothalamic-pituitary-adrenocortical (HPA) axis

A major mechanism of the stress response, involving three major constituents: the corticotropin-releasing hormone (CRH), corticotropin (ACTH), and glucocorticoids.

Molecular crowding

A term to denote a dense population of molecules (usually macromolecules) where aggregation, diffusion, hydration, and other properties of the individual molecules are significantly altered.

Introduction

Studies on crowding stress consider an exceptionally high number of variables. Consequences of crowding stress may differ greatly, depending on whether population density is raised by an increased number of species living in the same area or by reducing their living space. If crowding is increased to such an extent that it leads to confinement, malnutrition, or an increased incidence of infections, other complications develop. Crowding stress may be acute (transient), i.e., the effects manifest after a few days, or chronic, i.e., changes occur after prolonged overcrowding lasting for weeks, months, or even years. Stress conditioning (or stress tolerance) can be observed in crowding stress: repeated stress exposure significantly diminishes the acute stress-induced effects occurring later. While mice or rats are the most commonly used species in crowding stress experiments, studies have been performed with almost all types of domesticated animals, various birds, fishes, and even humans. Though the conclusions of these studies can be directly compared only within the same species, some general trends can be observed. This article focuses on these general aspects of crowding stress.

Crowding Stress: Psychosocial Effects

Crowding as a chronic source of stress constitutes a major threat to psychological well-being. Crowding leads to anxiety and social instability. Dense populations are characterized by considerably increased

aggressive behavior. Crowded monkeys (even well fed), including females and young, have brutal fights, wounding and killing each other. Crowding stress adversely affects gonadal functions, and if it occurs during pregnancy it may inhibit reproductive activity of even the second generation through masculinization of female pups. Chronic crowding leads to deficits in learning tasks and has been used in animal models to induce depression. In human populations, crowding stress evokes prominent psychosocial reactions: it is proposed to be an important factor in the development of increased urban insanity/schizophrenia. Moreover, substance abuse (alcohol, amphetamine, morphine, etc.) and addictive behavior are prompted by a stressful social environment, e.g., crowding stress.

Physiological Changes in Crowding Stress

Recently detailed studies were performed on the effect of crowding on birds. With increased brood size, nestlings of zebra finch *Taeniopygia guttata* grow less, and have decreased testosterone levels and a lower T cell response. These birds are significantly lighter and have shorter wing and tarsus length in adulthood. Females allocate less testosterone in the yolk of their eggs in crowded conditions. This hormone has a positive effect on the growth and muscular development of the embryos. Consequently, newborn birds already start with a growth deficit.

Crowding-related growth deficits can be observed and explained in a wider context. The average height of U.S. men becomes smaller by 1.75 inches (4.5 cm) as the population density increases from 55 persons per square mile to 60 000 persons per square mile. Obviously this change is affected by a large number of variables including the availability of health services, car use/abuse, pollution rates, and stress levels. However, small and big phenotypes seem to be well separated in several species including humans. Smalls are optimized for survival, while bigs were preferentially developed for proliferation. Smalls will develop and succeed under low resources (crowded conditions), while bigs prevail under ample resources (non-crowded conditions). Smalls and bigs properties are coded at the epigenetic level and are not readily interchangeable. As many as three generations may be needed for a phenotype switch from small to big or vice versa. A question for further exciting studies is how acute and prolonged crowding stress affect the switch between these phenotypes.

Crowding stress (especially if chronic) suppresses immune functions. Disturbed immune regulation leads to increased autoantibody levels and may be one of the factors behind the increased occurrence of childhood asthma. Various infections and increased

susceptibility to poisoning are more likely to occur under crowded conditions. A widely established example indicates that household overcrowding is related to an increased prevalence of ulcer-inducing *Helicobacter pylori* infections. *H. pylori* infections and stress-induced gastric lesions significantly contribute to the development of ulcers and stomach cancer. Due to digestive problems and occasional appetite loss, chronic stress induces weight loss. In several organs, such as in kidneys and adrenals, chronic crowding stress induces intensive amyloidosis. Chronic overcrowding in many cases leads to hypertension in the resting state or to relative hypertension after exercise.

Possible Molecular Mechanisms of Crowding Stress

Crowding stress activates the hypothalamic-pituitary-adrenocortical axis (HPA axis) and enhances basal level or reactivity of plasma corticosterone secretion. This stress-related stimulation is triggered by the corticotropin-releasing hormone (CRH) system. HPA stimulation by other HPA-related biochemical factors, such as vasopressin, carbachol, and nicotine, is significantly diminished under crowded conditions. Moreover, crowding considerably impairs the HPA axis response to cholinergic and adrenergic stimulations. The mechanism of crowding-induced inhibition is best known in the case of nicotine: social stress affects signal transmission from membrane nicotinic receptors of different subtypes through ion channels into the cell. Crowding stress seems to induce an adaptive response to the non-CRH-induced HPA response to avoid the overstimulation of this important regulatory mechanism.

Repeated, short stresses induced by restraint or crowding attenuate the acute restraint stress-induced stimulatory action of the HPA axis. This indicates the occurrence of stress tolerance (stress conditioning) in the HPA axis response to acute stress. As a possible mechanism a short hypersecretion of corticosterone may induce a prolonged feedback inhibition of the HPA axis activity.

HPA stimulation is possibly the cause of decrease in appetite and consequent weight loss. HPA stimulation leads to compromised immune function and suppression of gonadal functions. The latter effect has an important role in regulation of population size, decreasing the chance of fertilization. Chronic HPA stimulation may lead to osteoporosis, chronic gastrointestinal pain, and retarded growth. Thus, prolonged activation of the HPA axis may explain many of the psychological effects of overcrowding, such as gastrointestinal problems, weight loss, sensitivity to infections, and decreased reproductive activity.

Additionally, crowding stress induces lipid peroxidation and impairs cellular signaling mechanisms, especially in elderly subjects. Impaired signaling may significantly contribute to immune suppression and decreased adaptive mechanisms.

Crowding of Flies and Worms

Signaling mechanisms can be studied more easily in simple organisms. Larval crowding in the fruit fly, *Drosophila melanogaster*, induces HSP (heat shock protein) expression and leads to increased adult longevity and adult thermal stress resistance. Flies that had been exposed to larval crowding exhibit greater starvation resistance and lipid content than populations that did not experience larval crowding. Crowding suffered in larval stage suspends the usual buffering of phenotypic variation: adults of crowded *D. melanogaster* larvae display an increased variability of thorax and wing length, as well as sternopleural and abdominal bristle number.

Food limitation and overcrowding also induce arrested development of the worm, *Caenorhabditis elegans*, leading to the formation of the so-called dauer larva. Daf-7, a homolog of the human transforming growth factor- β (TGF- β), prevents dauer larva commitment. Several other members of the dauer larva regulating Daf family are receptor serine-threonine kinases similar to the human TGF- β receptor. Mutations of another signaling pathway of *C. elegans* may quadruple the adult lifetime of the worm in addition to disturbing its dauer larva development. Thus, disturbances in signaling due to crowding stress may have profound consequences in the longevity of (simpler) organisms.

Cell Crowding

Experimenters often use cell cultures, where the cell density may be much smaller than under physiological conditions. During their proliferation, cells increase their density (in adherent cell lines the culture approaches confluency), and cell crowding may gradually develop. Cell crowding significantly alters the efficiency of autocrine and paracrine hormonal regulation and profoundly changes the influence of neighboring cells as well as the extracellular matrix on the individual cells. Cell crowding usually diminishes cell proliferation. However, tumor cells may escape from this control by expressing various molecules such as integrin $\alpha V\beta 6$ or lytic enzymes against components of the extracellular matrix. The extent of cell crowding should be always considered when interpreting the physiological relevance of experimental results with cell cultures.

Molecular Crowding

If the total volume of a macromolecular species occupies a significant fraction of the total volume of the solution, we refer to such a medium as crowded. Under experimental conditions molecular crowding is induced by polyethylene glycol or by dextrane. An intracellular environment, where the total amount of macromolecules usually occupies more than one-third of the total volume, is a typical example of molecular crowding.

Molecular crowding exerts profound quantitative effects on macromolecular interactions in living systems and induces an increased association of macromolecules. Crowding reduces diffusion rates. As a compensatory mechanism, it enhances channeling between enzymes catalyzing consecutive enzyme reactions as well as improves signaling efficiency in organized signaling cascades. By extending the range of intracellular conditions, where macromolecular interactions occur, crowding acts as a metabolic buffer.

Another potential outcome of molecular crowding is the effect on the properties of cellular water. The crowded environment in the cell results in a significant decrease of the proportion of cellular water being in contact with macromolecules such as proteins and DNA. Macromolecules begin to compete for water molecules, their hydration becomes compromised, and, consequently, osmotic stress occurs. The large amount of macromolecules and their immobilized hydrate shell constitute a large excluded volume. Thus, macromolecular crowding affects all those biochemical process in which a change of excluded volume occurs. Such a process is the collapse of newly synthesized polypeptide chain into compact functional proteins, the unfolding of proteins induced by stress, and the association of proteins into nonfunctional aggregates such as plaques in human amyloid diseases.

In conclusion, molecular crowding has a profound effect on the chemistry of life via its influence on association of macromolecules and on the cellular water properties.

Conclusions

Crowding may occur at various levels, from molecules through cells to organisms. Elements of crowded populations have an increased chance for extensive interactions, which increases community formation but may also lead to a high number of unspecific interactions, against which the elements have not previously developed an adaptive response. The unusual effects behave as perturbations of the elements and may lead to their destabilization – thus

crowding stress occurs. Crowding stress profoundly affects the behavior of the element at all levels studied, be it a molecule, a cell, or a simple or higher organism up to humans. Crowding often leads to the reduction of the element number either by diminishing the birth of new elements or by destabilizing, segregating, and/or destroying previously existing elements. This article gave a number of examples of these changes.

Culture as Adaptation

Cultural Stress

Acculturative Stress

Glossary

- Acculturation** A process of cultural and psychological change that results from contact between two cultural groups.
- Adaptation** A process of change that seeks to improve the fit between cultural groups and/or individuals and their habitat; it may result in outcomes that range from well-adapted to maladapted.
- Culture** A shared way of life of a group of people, including their symbolic, social, and material products; cultures are transmitted to new members over generations.

<i>Ecology</i>	The study of relationships between human organisms and their physical habitats, including their biological, cultural, and psychological adaptations to these habitats.
<i>Strategies</i>	Various ways employed by cultures and individuals to adapt to their habitats, including adjustment, reaction, and withdrawal (e.g., coping strategies and acculturation strategies).
<i>Stress</i>	The cultural and psychological consequences that occur when changes exceed the capacity of groups and individuals to adapt.

Culture as Adaptation

Among the many approaches to understanding culture is the view that human groups develop a way of dealing with recurrent problems in their ecosystems; these solutions are widely shared among members of a society and transmitted to their offspring. That is, cultures are adaptive to context, and, to the extent that these adaptations are successful, their fit is enhanced and stress is reduced: "Culture is man's most important instrument of adaptation" (Cohen, 1968: 1). The empirical foundations for this conception of culture were laid by Forde and Kroeber, who demonstrated that in Africa and North America, culture areas generally mapped onto ecological areas; in both continents, broadly shared features of culture were associated with ecological features in a particular group's habitat. This conception of culture has permitted work in both anthropology and cross-cultural psychology to align with stress, coping, and adaptation frameworks that are widely used in psychology.

When ecological conditions are relatively stable and there is sufficient carrying capacity (i.e., support from the habitat), cultural adaptations are also stable. However, when there is ecosystem disturbance due to internal or external forces (such as natural disaster or invasion) or when there is a chronic shortfall in the ability of the habitat to sustain the cultural group, then new adaptations are required if the group is to survive. In these terms, ecosystem changes constitute stressors, attempts to find innovative ways to manage day-to-day existence constitute coping, and the solutions achieved (successful or not) constitute adaptation.

Concern with these two sources of influence (internal and external) has given rise to an ecocultural model that attempts to understand cultural and psychological phenomena as the result of adaptation to ecological factors and to those that arise from contact with other cultures (the process of acculturation). Both during the process and when there is limited

adaptive success, two kinds of stress may result: cultural stress and acculturative stress.

For both kinds of stress, it is useful to consider some fundamental strategies of coping with these internal and external stressors. There are at least three ways to achieve adaptation: adjustment, reaction, and withdrawal. In the case of adjustment, behavioral changes are in a direction that reduces the conflict (that is, increases the congruence) between the environment and the behavior by changing the behavior to bring it into harmony with the environment. In general, this variety is the one most often intended by the term adaptation and may indeed be the most common form of adaptation. In the case of reaction, behavioral changes are in a direction that retaliates against the environment; these may lead to environmental changes that, in effect, increase the congruence between the two, but not by way of cultural or behavioral adjustment. In the case of withdrawal, behavior is in a direction that reduces the pressures from the environment; in a sense, it is a removal from the adaptive arena. These three varieties of adaptation are similar to the distinctions in the psychological literature made between moving with or toward, moving against, and moving away from a stimulus.

Cultural Stress

As noted previously, cultural stress occurs when extant or novel situations within the culture place demands on the group and its individual members that exceed their capacity to respond. Rather than maintaining or improving their fit, the responses of the group and individuals fail, and adaptation is unsuccessful. From the point of view of ecological anthropology, examples of successful adaptations are the most common; this is because those that are not successful fail to survive and are unavailable for contemporary observation. However, archaeology provides numerous examples of cultures that disappeared as a result of failure to adapt. Despite this imbalance in cases, there are examples of societies and individuals under cultural stress due to the extreme circumstances that they face at present. Two of these are the Ik of northern Uganda and the Mossi and Fulani of Burkina Faso.

The classic portrayal of the Ik was presented by Turnbull. This cultural group had lived for centuries as hunting and gathering nomads in a semidesert region at the intersection of Uganda, Sudan, and Kenya. Their main territory was a valley that had been taken over by the government to create a national park, from which they were excluded. With their old economic subsistence base taken away and agriculture impossible, they attempted to survive by

raiding the cattle herds of neighboring groups. As the carrying capacity of their territory was reduced (exacerbated by failure of the rains), the social fabric of the Ik deteriorated. According to Turnbull, they “abandoned useless appendages . . . those basic qualities such as family, cooperative sociality, belief, love, hope and so forth, for the very good reason that in their context, these militated against survival” (1972: 289).

This portrait is one of extreme ecological change, one that was rather quickly followed by social, cultural, and psychological change, all of them maladaptive. In this extreme case, the stressors were so severe that the cultural resources were incapable of providing any coping strategies other than intense striving for individual survival. Severe hunger generated “loss of any community of interest, familial or economic, social or spiritual” (Turnbull, 1972: 157) and eventually resulted in a maladaptive “everyone for himself” strategy that in the end failed.

A second example of cultural stress, one that also resulted from ecological change, is that of two groups in the Sahel region of West Africa. Ongoing environmental degradation (deterioration of the soil, loss of nutrients, reduction in wildlife) has led to loss of food resources and income and constituted a major set of stressors in the lives of two societies in this region. The Fulani (pastoralists) and the Mossi (agriculturalists) had differentially adapted to this semiarid ecosystem, one grazing their cattle over a large territory, the other enclosing small land areas for cultivation. In this study, coping with environmental change was directly assessed (by questionnaire), as was their locus of control and two psychological outcomes (feelings of marginality and of personal stress). With respect to coping, two factors emerged, the first representing a combination of problem solving and support seeking and the second mainly avoidance strategies; this split resembles the Lazarus and Folkman distinction between problem-focused and emotion-focused coping. For the locus of control measure, three factors were obtained: the first represented individual effort, the second nonpersonal control, and the third was uninterpretable. Both the marginality and stress scales produced single factors.

Structural analyses of the impact of ecological and cultural factors on the two psychological outcomes were carried out. The carrying capacity of the ecosystem was introduced as the latent variable, with four variables (environmental degradation, land use, cattle, and modernity) used as independent variables. The ecosystem provided a higher carrying capacity for the pastoralists than for the agriculturalists, and consequently the former were less marginalized and stressed. According to Van Haaften and Van de Vijver

(1996: 426), “this finding is in agreement with the common observation that nomadic people (the pastoralists) are less susceptible to environmental stressors than are sedentary people (the agriculturalists). Unlike the latter, the former can move away from environmental stressors.”

With these two examples, it is possible to identify links between ecological, cultural, and psychological changes in human populations. Evidence from these anthropological and psychological sources shows clearly that when cultural groups experience stressors, collective and individual coping sometimes leads to successful adaptation but sometimes does not, resulting in stress.

Acculturative Stress

When ecosystem and cultural changes are introduced from outside, the process of acculturation is initiated. In essence, acculturation refers to both the cultural and psychological changes that follow from contact between two or more cultural groups. At the cultural group level, these changes can occur in the physical, political, economic, or social domains (e.g., urbanization, loss of autonomy and livelihood, and the reorganization or even the destruction of social relationships). At the individual level, changes in the psychology of the individual take place.

It had been previously thought that acculturation inevitably brings social and psychological problems. However, such a negative and broad generalization no longer appears to be valid. Variability in psychological acculturation exists and is associated with three differing views about the degree of difficulty that is thought to exist during acculturation: behavioral shifts, acculturative stress, and psychopathology. The first is one in which changes in an individual's behavioral repertoire take place rather easily and are usually nonproblematic. This process encompasses three subprocesses: culture shedding, culture learning, and culture conflict. The first two involve the selective, accidental, or deliberate loss of behaviors and their replacement by behaviors that allow the individual a better fit with the larger society. Most often this process has been termed adjustment, since virtually all the adaptive changes take place in the acculturating individual, with few changes occurring among members of the larger society. These adjustments are typically made with minimal difficulty, in keeping with the appraisal of the acculturation experiences as nonproblematic. However, some degree of conflict may occur, in which incompatible behaviors create difficulties for the individual.

When greater levels of conflict are experienced, and the experiences are judged to be problematic but

controllable and surmountable, then acculturative stress is the appropriate conceptualization. Drawing on the broader stress and adaptation paradigms, this approach advocates the study of the process of how individuals deal with acculturative problems on first encountering them, and over time. In this sense, acculturative stress is a stress reaction in response to life events that are rooted in intercultural contact. Within this orientation, depression (due to cultural loss) and anxiety (due to uncertainty about how to live) were the problems most frequently found in a series of studies in Canada. More recently, general and acculturation-related sources of immigrants' stress have been differentiated in the literature. It was found that acculturation-specific hassles, above and beyond general hassles, had a negative effect on psychological distress. In-group hassles of Vietnamese immigrant students, i.e., stressors that result from interactions with Vietnamese peers and family, and out-group hassles of Iranian immigrants, i.e., stressors that result from interactions or lack of interactions (perceived or real) with out-group members in Canada, were associated with depression.

When major difficulties are experienced, the psychopathology perspective is most appropriate. According to this perspective, changes in the cultural context exceed the individual's capacity to cope because of the magnitude, speed, or some other aspect of the change, leading to serious psychological disturbances such as clinical depression and incapacitating anxiety.

Long-term adaptation to acculturation is variable, ranging from a well to poorly-adapted situation in which individuals can manage their new lives very well to one in which they are unable to carry on in the new society. Short-term changes during acculturation are sometimes negative and often disruptive in character. For most acculturating individuals, however, after a period of time, some long-term positive adaptation to the new cultural context usually takes place.

Variations in adaptation result in part from the acculturation strategy adopted by individuals. These strategies derive from individuals orienting themselves to two fundamental issues faced during acculturation: (1) To what extent do individuals seek to maintain their heritage culture and identity? (2) To what extent do they seek to have contact with and participate in the larger society? These two issues can be responded to along two attitudinal dimensions, with generally positive or negative (yes or no) responses at opposite ends. Orientations to these issues intersect to define four acculturation strategies. From the point of view of nondominant groups, when individuals do not wish to maintain their cultural identity and seek daily interaction with other

cultures, the assimilation strategy is defined. In contrast, when individuals place a value on holding on to their original culture and at the same time wish to avoid interaction with others, the separation alternative is defined. When there is an interest in maintaining one's original culture while in daily interactions with other groups, integration is the option; here, there is some degree of cultural integrity maintained while at the same time seeking, as a member of a cultural group, to participate as an integral part of the larger social network. Finally, when there is little possibility or interest in cultural maintenance (often for reasons of enforced cultural loss) and little interest in having relations with others (often for reasons of exclusion or discrimination), marginalization is defined. Acculturation strategies have been shown to have substantial relationships with positive adaptation: integration is usually the most successful, marginalization is the least, and assimilation and separation strategies are intermediate.

Adaptation is also multifaceted. It can be primarily internal or psychological (e.g., sense of well-being, self-esteem) or sociocultural, linking the individual to others in the new society (e.g., competence in the activities of daily intercultural living). Other forms of adaptation, including marital adaptation and economic adaptation, have also been proposed in the acculturation literature.

Each of these four domains of adaptation to acculturation may entail acculturative stress. In all four, the source of the stressors lies in the contact between groups and the resulting process of cultural change. It is important to note that acculturative stress is not a unique form of stress, but has unique antecedents (residing in the process of acculturation). Moreover, many of the outcomes are closely linked to the unique features of the acculturation process (such as experiencing cultural identity problems, acquiring culturally appropriate social skills, rearranging marital relations to take new cultural expectations into account, and experiencing difficulties due to employment discrimination in the new society). Thus, acculturative stress can be said to be a special kind of stress because of both its special set of stressors and its special set of outcomes. Following are examples of these four facets of acculturative stress.

The initial distinction between psychological and sociocultural adaptation was proposed and validated by Ward and colleagues. As noted earlier, psychological adaptation mostly involves one's psychological well-being and satisfaction in a new cultural context, whereas sociocultural adaptation refers to one's ability to acquire culturally appropriate knowledge and skills and to interact with the new culture and manage daily life. Conceptually, these two forms of

adaptation reflect two distinct theoretical approaches to acculturation. Psychological adaptation is better interpreted in terms of a stress and coping model; sociocultural adaptation is better viewed from a social learning perspective. Stress and coping models are based on the notion that both positive and negative life changes are intrinsically stressful in that they require adaptive reactions. Acculturation has been viewed as entailing such stress-inducing life changes, which increase susceptibility to physical and mental illness. The second approach draws on a combination of social skills and culture learning models. Individuals experiencing culture change are socially unskilled in the new cultural setting. Social learning models emphasize the importance of the acquisition of social skills and knowledge appropriate to the new culture.

While conceptually distinct, psychological and sociocultural adaptation are empirically related to some extent (correlations between the two measures are in the 0.4 to 0.5 range). However, they are also empirically distinct in the sense that they usually have different experiential antecedents. Research has shown that psychological adaptation, defined in terms of well-being or mood states (e.g., depression, anxiety, stress), is predicted by personality, life changes, and social support variables. Locus of control, life changes, and personal relationship satisfaction accounted for a substantial portion of variance in psychological well-being in student and adult sojourners. In contrast, assessed in terms of social difficulty, sociocultural adaptation was predicted by variables that are related more strongly to cognitive factors and social skills acquisition, such as cultural knowledge, cultural distance, cultural identity, language ability, length of residence in the new culture, and amount of contact with hosts. Extending this framework to immigrant couples, Ataca and Berry also found that these two dimensions of adaptation were associated with different variables. Psychological adaptation of married Turkish immigrant couples in Canada was associated with the personality variable of hardiness, social support, acculturation attitudes, and perceived discrimination, while sociocultural adaptation was mostly related to variables that are instrumental in acquiring social skills in the new culture, namely, English language proficiency and contact with Euro-Canadians.

Ataca and Berry also introduced the concept of marital adaptation, which relates to the accommodation of spouses in the process of acculturation when each is faced with the new culture and forms of behavior and different ways of acculturating. Their findings supported the distinctiveness of

marital adaptation from psychological and sociocultural adaptation. Better marital adaptation was mostly associated with variables specific to marital life, namely, fewer marital stressors and greater marital support; yet, marital variables also displayed close relations with psychological adaptation. This is in line with the literature on the relationship between marital variables and psychological distress among immigrants. Marital stressors were found to have an impact on both the marital distress and the depressive and psychosomatic symptoms of Indo-Canadian women. Naidoo found that South Asian women in Canada who had supportive husbands were less stressed. While the marital life of Turkish immigrants was related to psychological well-being, it was unrelated to sociocultural adaptation. The social skill learning necessary to function in the new cultural context was neither impeded nor facilitated by the conjugal relationship.

A fourth aspect of adaptation, that of economic adaptation, refers to the process by which individuals cope with and reestablish sustainable work relationships in the new economic system (including problems of status loss, under- or unemployment, and status mobility). Immigrants typically suffer high rates of under or unemployment. Lack of knowledge of language, lack of training, and discrimination force many immigrants into low-skill jobs. Conversely, high levels of education, occupational skills, and professional training received in the home country are often not recognized by authorities in the new country, resulting in underemployment. Under- or unemployment, low incomes, and the concomitant loss in one's socioeconomic status constitute sources of stress and are related to psychological symptoms. Aycan and Berry found that a greater decline in present status in Canada compared to the departure status from Turkey was associated with high acculturative stress among Turkish immigrants. Those who experienced greater status loss were also less satisfied and less likely to describe themselves as accomplished in economic life. The longer the immigrants were unemployed, the more likely they suffered from acculturative stress, negative self-concept, alienation from the society, and adaptation difficulties.

Studying the adaptation of both professional and nonprofessional Turkish immigrants in Toronto, Ataca and Berry found that those of low socioeconomic status were more stressed yet more satisfied with their lives than those of high socioeconomic status. This finding again points to the consequence of status loss that professional immigrants experience. Immigrants of lower status make comparisons with what their economic condition used to be like

and feel satisfied, while those of higher status make comparisons with their cohorts in Turkey and feel deprived. In this context, it was reported that low socioeconomic status and family income were also highly associated with high feelings of disturbance among South Asian women in Canada. Socioeconomic status is again an important predictor of stress in the studies with African American and Mexican American females and Korean American women.

Apart from personal factors, contextual factors are also important in the adaptation of immigrant and acculturating groups. Of utmost importance in the society of settlement are the attitudes of the dominant society. Perceptions and personal experiences of intolerance, hostility, and discrimination have been documented to serve as stressors and to have a negative impact on psychological adaptation.

In conclusion, stress does not take place in a vacuum: contextual factors, especially cultural ones that have been outlined here, clearly play a role. The importance of ecological and acculturative factors has been emphasized in order to provide a macro-level view of how stress and coping are shaped. Within these, micro-level experiences have been identified to illustrate the close links between culture and stress.

Cultural Transition in the Central Eastern European (CEE)
Countries as Field Experience
Changing Attitudes and Values and Cultural Transition

Glossary

- Chronic stress** According to the original concept of the general adaptation theory of Janos (Hans) Selye, the three phases of stress are alarm reaction, resistance phase, and, the physiologically most harmful phase, exhaustion, that is, chronic stress. Chronic stress theory incorporates the learned helplessness model, the psychosocial and psychiatric models of depression, the control theory of stress and health, and the concept of vital exhaustion.
- Cognitive appraisal** The interpretation of an event or situation with respect to one's attitudes, values, and well-being.
- Coping** Constantly changing cognitive and behavioral efforts to manage specific external and/or internal demands that are

*Depressive
symptomatology*

Learned helplessness

Social capital

Social status

appraised as taxing or exceeding the resources of the person.

Symptoms of mood disturbances characterized by negative thoughts (for example, feelings of helplessness, inadequacy, loss of control, and low self-esteem), decreased motivation and interest in life, and such physical symptoms as sleep disturbances and fatigue. In civilized countries the prevalence of depressive symptomatology is around 20%.

A condition of loss of control created by being subjected to unavoidable trauma (such as shock and relative deprivation). Being unable to avoid or escape (flight or fight) an aversive situation produces a feeling of helplessness that generalizes to subsequent situations. Learned helplessness is the best animal model of human depressive symptomatology.

Refers to features of social organization, such as trust, norms, and networks, that can improve the efficiency of society by facilitating coordinated actions. Indicators are levels of trust, perceived reciprocity, and density of membership in civic associations.

An individual's worth relative to other group members. This evaluation of worth must be at least tacitly understood and agreed upon by interacting individuals.

Sociocultural identification

Introjection of socially meaningful behavioral patterns (usually social roles), through significant persons, via nonverbal communication and contextual and situational cues, acquiring thereby also motivation to actualize the given behavior patterns in fantasy and in action. Learning by model, model following behavior, model learning, and imitation are behavioral descriptions of the same phenomenon. Identification is a psychoanalytic term, meaningful from a developmental and intrapsychic point of view.

Cultural Transition in the Central Eastern European (CEE) Countries as Field Experience

Cultural Transition and Health in CEE Countries

While in modern societies living conditions have improved in many respects, other aspects of life have been fundamentally damaged. Important factors of personality development, for instance, the mother-child relationship, social models of the extended family, and the order in which values are passed on, are being challenged. The accelerated pace of life and unpredictable environmental changes add to these factors. Therefore, it is understandable that in all developed countries the number of adults and children suffering from the symptoms of anxiety and depression has increased. Compared to other countries, more dramatic changes have been experienced in the suddenly changing CEE and Eastern European countries. For example, in Hungary the prevalence of severe depressive symptomatology increased from 2.9 to 7.1% between 1988 and 1995.

A unique field experience of cultural and socioeconomic transition has taken place in the CEE countries during the past several decades. Until the end of the 1970s, the mortality rates in the CEE countries, including Hungary, were better than those of Britain and Austria. Subsequently, whereas in Western Europe the life expectancy rose continuously, in the CEE countries, such as in Hungary, Poland, the Czech and Slovak Republics, and Romania, this tendency reversed. By 1990 the Hungarian mortality rate was the highest in Europe. This deterioration cannot be ascribed to deficiencies in health care, because during these years there was a significant decrease in infant mortality rate and improvements in other dimensions of health care. Until 1990 it was not due to a declining standard of living: between 1970 and 1988 the GDP rose by more than 200% in Hungary, and in 1988 the economic status of the lowest socioeconomic strata was even better than in 1970.

The changes in Hungary and other CEE countries since 1970 have been due to a gradually intensifying social and economic polarization. Whereas a large part of the population lived at nearly the same low level in 1970, by the end of the 1980s a large fraction of society had achieved a higher socioeconomic level, having obtained one or more cars, their own property, and substantially higher income. Gaps within society had consequently widened.

Multivariate analysis showed that it was not the relatively worse socioeconomic situation itself that resulted in the higher morbidity rates, but the subjective appraisal of the situation and the consequent chronic stress – not a difficult social situation itself, but the subjective experience of relative disadvantage was the most significant health risk factor. When, for example, an individual does not have a car and therefore feels disadvantaged and that he or she cannot properly provide for his or her family, this is the state of mind that intensifies deterioration of both mental and physical health.

Self-Destructive Cycles between Cultural and Socioeconomic Transition: Chronic Stress, Depressive Symptomatology, and Health

Returning to the original concept of the general adaptation theory of János Selye, the three phases of stress are alarm reaction, resistance phase, and, the physiologically most harmful phase, exhaustion, that is, chronic stress. Chronic stress theory could incorporate the learned helplessness model, the psychosocial and psychiatric models of depression, the control theory of stress and health, and the concept of vital exhaustion. Furthermore, such a unified stress model could best explain the morbidity and mortality crisis in the middle-aged male population in Central and Eastern Europe in the last decades. A self-destructive circle develops from the chronic stress of the enduring, relatively disadvantageous socioeconomic situation and depressive symptoms. This circle resulting in depressive symptoms plays a significant role in the increase of morbidity and mortality rates in the lower socioeconomic groups of the population. It is not the bad socioeconomic situation itself, but rather the subjective evaluation and cognitive appraisal of the relative disadvantage that seems to be the most significant risk factor of health deterioration, since at equal living standards, Hungarian and other health statistics were better than those of other European countries until the 1970s.

Amid rapid socioeconomic and cultural changes, those left behind can continually blame themselves or their environment, see their future as hopeless, and experience permanent loss of control and helplessness. Negative judgment of one's own situation

and feelings of powerlessness and loss of control are the main background factors in the development of a chronic stress situation that might result in depressive symptomatology. This view of life at a time when society is rapidly polarizing, especially when the only goal of most of society is individual advancement, becomes very common.

Paralleling the increase in socioeconomic gaps within society there was an enormous decrease in perceived social support and social capital and increase in the sense of loss of control, not only in individuals, but in masses of people who felt rejected. The sudden transition of society continuously created situations in which the psychological and physiological balance could be maintained only with great difficulty; accordingly, there was a need for a change in attitudes and ways of coping. Only people with flexible coping resources adapted successfully.

Health Consequences of Chronic Stress and Depressive Symptomatology

There are many possible explanations for chronic stress and the consequent depressive symptomatology having an important role in higher morbidity and mortality rates during periods of cultural and socioeconomic transition.

The depressive condition affects perceived state of health and can lead to disability even without organic illness. Depression has a very close relationship with self-destructive behaviors, such as smoking and alcohol abuse, and suicidal behavior is especially common among depressive people. Those suffering from permanent mood disorder and depression are more vulnerable to various diseases and are less able to improve their social situation, so that they easily fall into a sustained vicious cycle. In recent decades, depression, vital exhaustion, and hopelessness have been identified as important independent risk factors for coronary disease. Learned helplessness or learned hopelessness, which can be regarded as the most appropriate model for depression, is associated with decreased immunological activity and affects tumor growth and vulnerability to various infections.

Mediating Role of Social Cohesion and Social Capital

In recent years, studies have suggested that cultural and social identity, sociocultural identification, social capital, and social cohesion are among the most important health protection factors in modern societies. Where they exist, wealthier people are prepared to make sacrifices for the community, and the disadvantaged do not feel that they have been completely left

to themselves in a hostile world. Trust in each other, esteem for shared values, the acceptance and internalization of cultural and social identity result in a high level of social cohesion in the society, which is the foundation not only of health but also of economic wealth and prosperity.

Marmot, Kawachi, and Wilkinson, who drew attention to the fundamental risk of inequality within society, also considered the phenomena of social cohesion and social capital to be the most important factors behind differences between countries and regions. For a lower-level British civil servant, for example, it was not his or her relative poverty itself that was the cause of his or her bad health, because during German bombing the death rates of the London population greatly decreased despite difficult living circumstances. The weakening of social cohesion and social capital is a significant factor in the emergence of large social differences and the associated deterioration of health – not only in CEE countries, but also in the developed countries.

Changing Attitudes and Values and Cultural Transition

Psychological Definition of Freedom and Democracy

An important question is whether the crisis experienced in human communities nowadays is a necessary part of civilization. The latest results of behavioral science point out that, beyond the concomitant phenomenon of lifestyle, we can see the root cause of this crisis in the fact that in modern society new possibilities for arousing anxiety have taken place.

During previous centuries the basic optimization principles of life were survival, subsistence, and maintaining the family, which dominated people's behavior. As a result of technological development, focus on these principles are no longer fundamentally necessary in civilized countries. However, the previously fixed order and communal forms of passing on values have also ceased. A young person's self used to be formed on the basis of feedback from the family, the extended family, and contemporaries in the community of the village or small town in which he or she lived. Nowadays, this process takes places within a nuclear or broken family and through mass communication, which seemingly provides feelings of community, but in reality the person rarely receives the continuity of patterns and values with which they can identify themselves.

While there are undeniable benefits in the move away from more tight-knit, rule-bound traditional

societies, under the conditions of continuous cultural and socioeconomic transition, the loss of balance in the human–environment system becomes more apparent. A solitary, anxious human being, deprived of relationships, values, goals, and self-esteem, can be used for the necessary functions of society and can be arbitrarily changed and manipulated. So we must recognize that technological developments have established the preliminary conditions for creating anxiety.

In order to maintain or increase their power, the person or group who possesses the most information can afford to either deprive others of information or give it as a reward, thereby creating anxiety in the environment. Arousing anxiety is not only a means, but also the essence of a dictatorship. The most effective tactic employed by a dictator is to create anxiety. A dictator wants to assure total decisional freedom for him- or herself. This is characteristic of all dependent relationships, in which the least dependent has the right to deprive the other person of information and thus keep the other in a situation over which he or she have no control. This not only occurs in totalitarian societies, but also can happen in families, schools, or jobs. Thus, we encounter the abuse of power and different ways of arousing anxiety every day, but we still do not give these situations enough attention, we do not recognize them in their embryonic forms, and we do not understand how this slow-action poison kills.

We can also arrive at the psychological definition of freedom and democracy through understanding the essence of anxiety. In a psychological sense, freedom means possessing the necessary, essential information needed to evaluate, solve, and control our situation, and being able to contribute actively to shaping our situation. Democracy means these rights – both the right and the responsibility of information and action.

Misuse of Anxiety in Cultural Transition

How does this apparently purely psychological and medical phenomenon, anxiety, become a basic concept that can shape society? We can ask whether anxiety has an adaptive function: is there any need for anxiety? Imagine a completely anxiety-free person: he or she does not recognize prospective danger and hence does not avoid dangerous situations and cannot be controlled by social sanctions. Some criminals and people with antisocial personality disorder belong to this type. In such cases, those in their environment suffer while they themselves follow their momentary drives.

Social co-existence requires a certain degree of anxiety. One learns as a child in which situations to

expect punishment – a mother's frowning look or a bad mark in school. The avoidance of anxiety is a very important driving force from the first moments of life. If the rules of punishment are foreseeable and are commensurate with the mistakes made, then anxiety can have an adaptive function. But if the rules are opaque or do not exist, then the powerlessness and defenselessness can become a weapon in the hands of those who have power. If parents punish from a whim rather than for a reason, then the child will not understand and will not be able to understand when he is threatened by danger. If a teacher or university lecturer asks questions from material that the student could not learn, he or she hammers insufficiency and failure into the student. If leaders, managers, politicians, those who possess more information do not make the rules clear, then they assure their arbitrary authority by causing anxiety in deprived masses. The twentieth century has created the possibility of causing such total anxiety, spread by the mass communication media just as Hitler's or Stalin's radio speeches were transmitted by the loudspeakers of a whole empire.

It is obvious from the preceding that, since creating anxiety can involve issues of money, benefit, and power, there are enormous advantages in knowing how to deal with these powers effectively. Films, newspapers, magazines, and books infiltrate the community and human relationships and can belittle or deny values and mold people into a mass that can be led. This type of mass manipulation can occur even if the manipulator's aim differs from what actually takes place.

The ideology of the consumer society, to control human behavior through the liberation of instincts and search for pleasure, degrades human beings to the level of animals since an animal's decisions are influenced by its instincts to preserve its physiological balance. To achieve dominance by any means is a natural need in such a system.

On every level of society there is, day by day, a life-and-death struggle between two behaviors: either accepting and respecting other people, establishing agreement and a community of free people and bringing the value of democracy into being or arousing anxiety by withholding information from others. Not the slogans but the behavior classifies the participants.

The question is whether humans will be able to adapt themselves to the circumstances formed by history, or whether their lack of adaptive ability will lead the human race into extreme peril. This adaptation has to be realized on the level of both the individual and society.

Transsphenoidal surgery (TSS)

Surgical procedure of choice to remove pituitary tumors. This procedure utilizes the nasal approach, avoiding the necessity of opening the skull.

Epidemiology

The overall incidence of spontaneous Cushing's syndrome (CS) is approximately two to four new cases per million of population per year, with a female to male preponderance. Approximately 10% of these cases occur in children and adolescents. Adrenocorticotrophic hormone (ACTH)-dependent CS accounts for about 85% of endogenous cases in adults, adolescents, and children older than 7 years of age (**Table 1**). Cushing's disease is responsible for 80% of these cases; the remaining 20% is caused by ectopic ACTH or, very rarely, ectopic corticotropin-releasing hormone (CRH) secretion. Benign cortisol-secreting adenomas or adrenocortical carcinomas are rare and account for 10–15% of endogenous cases in children older than 5. In children younger than 5, adrenocortical carcinomas and primary pigmented nodular adrenal disease (PPNAD) are the more frequent causes of endogenous CS. Primary pigmented nodular adrenal disease is a form of adrenal tumors that occurs frequently in association with Carney complex, a multiple endocrine neoplasia and lentiginosis syndrome. With the increasing utilization of glucocorticoids for a wide range of nonendocrine diseases, the exogenous, iatrogenic CS has become more frequent and is more prevalent than the endogenous forms.

Glossary

Adrenocorticotrophic hormone (ACTH)
Corticotropin-releasing hormone (CRH)
Cushing's syndrome

Pituitary hormone stimulating release of adrenal glucocorticoids.

The main regulator of the endocrine stress axis. Stimulates pituitary ACTH.

Caused by the state of hypercortisolemia.

Table 1 Classification of Endogenous Cushing's Syndrome and Rate of Occurrence in Children Older than 7 Years^a

<i>Classification</i>	<i>Percentage</i>
ACTH-dependent	85
Pituitary (Cushing's disease) (includes MEN-I)	80
Ectopic ACTH (includes MEN-I)	20
Ectopic CRH	Rare
ACTH-independent	15
Adrenal adenoma (includes MEN-I)	30
Adrenal carcinoma	70
Primary pigmented adrenocortical disease (PPNAD)	0.5–1
McCune-Albright's syndrome	Rare
"Transitional states"	Rare

^aModified from Magiakou and Chrousos (1994).

Etiology

Endogenous CS results from increased secretion of cortisol by the adrenal cortex and is due to ACTH hypersecretion (ACTH-dependent CS) or the autonomous hyperfunction of the adrenocortical cells (ACTH-independent CS). Some forms of ACTH-independent CS have recently been discovered to be due to aberrant expression of neuroendocrine or cytokine receptors (such as GIP, vasopressin, β -receptor, or interleukin-1), putting the adrenal tissue under a tropic stimulus, which is not under the control of the regular negative feedback. Cushing's disease, the ACTH-dependent form of endogenous CS, is due to an ACTH-secreting, benign corticotroph tumor of the anterior pituitary gland. Ectopic ACTH-secreting tumors occur mostly in patients with bronchial carcinoma. In addition, other tumors may present with ectopic ACTH production (thymus, liver, renal carcinoma, etc.). Exogenous CS results from chronic administration of glucocorticoids (for treatment of neoplastic, autoimmune, and other diseases) or ACTH (for the treatment of certain seizure disorders).

Pathophysiology

The main stimulus for the release of cortisol from the adrenal cortex is ACTH, which is produced by the corticotrophs of the anterior pituitary, which, in turn, are under the regulatory influence of hypothalamic CRH and vasopressin (Figure 1). The ambient plasma free cortisol levels regulate ACTH secretion in a negative feedback fashion. Normally, less than 10% of plasma cortisol is in the free form, with the majority being bound to cortisol-binding globulin (or transcortin).

In the physiological state, ACTH and cortisol have a circadian pattern of secretion, established early in infancy and in accordance with other human

circadian biological activities. The peak of ACTH and cortisol secretion occurs in the morning (between 7:00 and 8:00 a.m.) and is lowest in the late evening hours (around midnight). This physiological circadian rhythm is blunted in CS.

The adrenals have an amazing ability to adapt to states of hyper- or hypofunction. They use more than 10 times the cardiac output and blood volume that would correspond to their organ weight. Therefore, they are unique in demonstrating signs of hormonal excess and stress. Chronic stimulation of adrenal tissue with ACTH in Cushing's disease or ectopic ACTH-secreting tumors will cause hypertrophy of the adrenals, leading in particular to an increase in size of the zona fasciculata. The adrenal cortex undergoes hypervascularization and the cells increase in mitochondria, smooth endoplasmic reticulum, and filopodia, indicating increased activation of steroidosynthesis.

Glucocorticoids are vital for survival because they participate greatly in the stress response of humans. Glucocorticoids affect all tissues and organ systems, and the glucocorticoid receptor is ubiquitously present. Glucocorticoids have profound catabolic activities: they inhibit growth and reproduction, promote proteinolysis, and suppress the immune and inflammatory reaction. These effects are behind some of the cardinal clinical manifestations of CS: delayed growth and bone maturation, hypogonadism, dermatopathy, loss of muscular tissue, and frequent fungal or saprophytic infections.

Clinical Picture

Table 2 summarizes the clinical features of CS in children and adolescents. An early and common sign in almost all patients is obesity, which is generalized or truncal and is characterized by moon facies (facial rounding) and plethora. Growth retardation or complete arrest is present in 90% of the children. Other clinical manifestations include sleep disturbances, muscle weakness and fatigue, hirsutism, and typical purple skin striae. Hypertension, carbohydrate intolerance or diabetes, amenorrhea, advancement or arrest of pubertal development, and easy bruising or spontaneous fractures of ribs and vertebrae may also be encountered. Although all patients may exhibit some of these features at the time of diagnosis, few, if any, will have all of them. Photographs of the patient, taken over a period of years, are helpful in the clinical evaluation.

The clinical presentation can identify the cause of CS in children and adolescents. Thus, severe and rapidly progressing CS points toward an adrenal neoplasm or, although rare in children, ectopic ACTH syndrome. Patients with adrenocortical carcinomas

may be asymptomatic or may have abdominal pain or fullness, symptoms and signs of CS (30%), virilization (20%), combined symptoms of CS and virilization (30%), feminization (10%), or hyperaldosteronism (5–10%). CS is periodic or intermittent in a significant percentage (~10%) of children and adolescents.

Laboratory Findings

The first step in diagnosing noniatrogenic CS is the biochemical documentation of endogenous hypercortisolism, which can usually be accomplished by outpatient tests. The first test is measurement of 24-h urinary free cortisol (UFC) excretion corrected for body surface area and/or the determination of 24-h urinary 17-hydroxycorticosteroid (17OHCS) excretion (corrected per gram of excreted creatinine). UFC excretion is a good first-line test for documentation of CS, with, assuming correct collection, very few false negative results. The second test is the single-dose dexamethasone suppression test. The overnight 1-mg (in young children, 15 µg/kg body weight) dexamethasone suppression test is a useful screening procedure for hypercortisolism. It is simple, with a low incidence of false normal suppression (less than 3%). The same test, however, has

a high incidence of false positive results (approximately 20–30%). A plasma cortisol level >1.8 µg/dl (50 nmol/l) suggests endogenous hypercortisolism and needs to be followed by a 24-h urine collection for determination of UFC or 17OHCS levels.

CS is generally excluded if the aforementioned tests are normal, although one should remember that periodic and intermittent cortisol hypersecretion, which may occur in patients with CS of any etiology, may confuse the picture.

In the past few years, a simple test reached importance in the first-line diagnosis of CS, especially for outpatient assessment. The measurement of late-night salivary cortisol is easy, and the cortisol in this test is stable under room conditions. Because of the variety of the diagnostic ranges in this test, the cut-off point of the local laboratory has to be known. The sensitivity and the specificity of this test are between 95 and 98%.

Another important and highly sensitive test is the measurement of the midnight sleeping or awaking cortisol levels, because of the circadian rhythm of cortisol secretion in healthy persons. A sleeping midnight cortisol level of less than 1.8 µg/dl (50 nmol/l) excludes CS. Once CS has been diagnosed, the differential diagnosis is investigated via dynamic testing of the function of the hypothalamic-pituitary-adrenal (HPA) axis as well as imaging studies. It is essential that dynamic endocrine testing is performed while the patient is hypercortisolemic, and, in order to avoid mistakes, this state should always be documented at the time of testing. All adrenal blocking agents should be discontinued for at least 6 weeks prior to testing.

The major tests in the differential diagnosis of CS and their interpretations include the following (see also [Figure 1](#)):

1. Low-dose dexamethasone suppression test and dexamethasone-CRH test: The low-dose dexamethasone suppression test (0.5 mg every 6 h over 2 days) and the dexamethasone-CRH test are reliable procedures for differentiating Cushing's disease from subclinical CS. In the combined dexamethasone-CRH test, after application of 0.5 mg dexamethasone every 6 h over 2 days (start on first day at 12.00 a.m.; the finish dose is given at 6.00 a.m.), a CRH-stimulating test will follow at 8.00 a.m. If the plasma cortisol is lower than 1.4 µg/dl (38 nmol/l) after 15 min, the CS is excluded. In subclinical CS, the cortisol is depressed at this time.
2. CRH stimulation test. The ovine (o) CRH test is of greater value than the dexamethasone suppression test in differentiating Cushing's disease and ectopic ACTH syndrome.

3. Overnight 8-mg dexamethasone suppression test. This test is currently not recommended for routine use. Because of its sensitivity of about 80% of cortisol suppression in CS, it yields no further information than the low-dose test.
4. Petrosal-sinus sampling with CRH test. This procedure can help to differentiate between a pituitary and a non-pituitary source of corticotropin secretion: if there is a ratio of two between basal central and basal peripheral sampling of corticotropin, or after stimulation with CRH a ratio of three, the diagnosis of Cushing's disease is clear.

Radiographic Findings

Imaging techniques can help clarify the etiology of hypercortisolism. These include computed tomographic (CT) scanning and magnetic resonance imaging (MRI) of the pituitary gland and CT scan, MRI, and ultrasound imaging of the adrenal glands. CT and MRI scans of the chest and abdomen are also used when tumors secreting ectopic ACTH are suspected.

Treatment

The preferred treatment for CS depends upon the specific cause of the hypercortisolism, which must be firmly and unequivocally established. The optimal treatment is correction of hypercortisolism without permanent dependence on hormone replacement.

Cushing's Disease

Transsphenoidal surgery (TSS) Transsphenoidal surgery is the treatment of choice for most cases of CS caused by pituitary microadenomas. It is indicated if the presence of a pituitary microadenoma can be demonstrated preoperatively by imaging techniques or bilateral inferior petrosal sinus blood sampling (BIPSS). In most specialized centers, the success rate of first TSS exceeds 90%. If BIPSS has lateralized the microadenoma and the surgeon cannot identify it at surgery, 75–80% of patients can be cured by ipsilateral hemihypophysectomy. Usually, successful TSS leads to the cure of hypercortisolism without using permanent glucocorticoid replacement. Approximately 5% of patients suffer recurrences; this is most common in patients with pituitary macroadenomas. The success rate of repeat TSS is considerably lower (approximately 50–60%). Complications include transient or permanent, partial or complete anterior pituitary insufficiency, including, in order of frequency, hypothyroidism, growth hormone deficiency, hypogonadism, and adrenal insufficiency. Transient diabetes

insipidus and inappropriate antidiuretic secretion syndrome are also common. Success after TSS is defined as a decrease in serum cortisol or UFC to an undetectable level in the immediate postoperative period. After a successful TSS, a period of adrenal insufficiency occurs in most patients cured, during which glucocorticoids must be replaced at a dose of 12–15 mg/m²/day. This abnormality of the HPA axis can last as long as a year or longer. It is rare, though possible, that it is permanent. The replacement dose of hydrocortisone is maintained for 3 months, and adrenocortical function is evaluated at that time with a rapid Cortrosyn test (250 mg ACTH 1–24 iv bolus, with plasma cortisol measured at 0, 30, and 60 min). If the test is normal (cortisol >18 and >20 µg/dl (500 nmol/l and 550 nmol/l) at 30 and 60 min, respectively), glucocorticoid replacement is discontinued. If the response is subnormal, the patient is reevaluated at 3-month intervals. About 70–80% of the patients will have a normal test at 6 months postoperation. Patients should be given extra glucocorticoids during stress (two times replacement dose for minor stress such as febrile illness or dental surgery, and 8–10 times replacement dose for major stress, such as major trauma or surgery).

Pituitary X-radiation with or without mitotane This is an alternative treatment that may be used after failure of TSS, when there is presence of cavernous sinus wall invasion by the tumor, or in patients judged unsuitable for surgery. The total recommended dosage of pituitary irradiation is 4500 to 5000 rad. High-voltage, conventional X-radiation is administered in 180- to 200-rad fractions over a period of 6 weeks. Success rate is ~40–50%, without mitotane and ~80% with mitotane (see later).

Pharmacotherapy Drug therapy alone is rarely used to treat Cushing's disease, except temporarily, prior to definitive treatment. Mitotane (Lysodren) is the only available pharmacological agent that both inhibits biosynthesis of corticosteroids and destroys adrenocortical cells secreting cortisol, thus producing a long-lasting effect. Therapy with mitotane (up to 3 g/day) is usually combined with radiotherapy. Aminoglutethimide, up to 1 g/day orally in four divided doses, or metyrapone, up to 1 g/day in four divided doses, may also be used alone or in combination with mitotane. During treatment, UFC excretion should be monitored and the regimen should be titrated to maintain this parameter in the normal range. If adrenal insufficiency is suspected, oral hydrocortisone should be added.

Ketoconazole (up to 1400 mg/day or 20 mg/kg/day) or trilostane have also been used alone or in combination with mitotane to control some of the symptoms and metabolic abnormalities associated

with Cushing's disease. Combinations are recommended because they usually prevent breakthroughs that occur when the drugs are used alone. In addition, one can use moderate doses with less side effects from each agent.

There are also new compounds such as fluconazole and glitazones, and for ectopic CS there are somatostatin analogs such as octreotide, lanreotide, and cabergolin.

Bilateral adrenalectomy The indications for this procedure have been dramatically changed by the success and low morbidity of TSS. Bilateral adrenalectomy is a possible treatment for patients who have failed selective pituitary adenomectomy or hemihypophysectomy. The major disadvantages of this surgery are that the individual is committed to lifelong daily gluco- and mineralocorticoid replacements, it does not eliminate the cause underlying the hypersecretion of ACTH, and relapses, though rare, may occur as a result of growth of adrenal rest tissue or an adrenal remnant. Furthermore, perioperative mortality is approximately three times higher than that of TSS, although it can be minimized by careful perioperative preparation. Also, Nelson syndrome (i.e., large pituitary macroadenomas secreting great amounts of ACTH and lipotropin resulting in skin hyperpigmentation) may occur in approximately 10–15% of patients with Cushing's disease treated with bilateral adrenalectomy. These tumors can impair vision and should be treated surgically and by radiotherapy.

Ectopic ACTH-Dependent CS

The preferred treatment for ectopic ACTH secretion is surgery aimed at completely excising the tumor, if resectable and of known location. If there is evidence of adjacent lymph node invasion, local radiation can be recommended after surgery for some tumors, such as carcinoids. If surgical resection is impossible or if the tumor is hidden, blockade of steroidogenesis is indicated; if necessary, bilateral adrenalectomy is considered.

Neuropsychiatric Symptoms in Patients with Spontaneous Untreated Cushing's Syndrome

Improvement in Neuropsychiatric Symptoms after Treatment

Brain-Imaging Studies in Cushing's Syndrome

Mechanisms for the Behavioral Effects of Cortisol

Glossary

<i>Hippocampus</i>	A brain structure that is part of the limbic system and key to learning and memory.
<i>Libido</i>	Desire for sexual activity.
<i>Mental status evaluation</i>	Standard bedside clinical tests used to examine mental functions.
<i>Neuropsychological studies</i>	Tests of various aspects of cognition, including verbal functions, visuospatial functions, learning, and memory.
<i>Sleep electroencephalogram (EEG)</i>	An electroencephalogram taken during sleep to measure brain electrical activity and study the structure of sleep.

Cushing's disease, the major type of spontaneous Cushing's syndrome, is the classic endocrine disease characterized by hypersecretion of cortisol. Intriguingly, emotional disturbances were already recognized as a feature of the disease in Harvey Cushing's original description in 1932. This association was then confirmed by retrospective chart reviews. More recently, studies of patients with spontaneous Cushing's syndrome examined prior to treatment have characterized the disturbance and shown that the majority manifest clinical features similar to those seen in patients with a primary psychiatric depressive disorder. Patients with Cushing's disease and syndrome exhibit a consistent constellation of symptoms, including abnormalities in mood (irritability and depression), vegetative functions (decreased libido and increased insomnia), and cognitive functions (decreased concentration, learning, and memory).

Neuropsychiatric Symptoms in Patients with Spontaneous Untreated Cushing's Syndrome

Mood and Affect

Irritability, a very frequent symptom seen in close to 90% of patients, is usually the earliest behavioral symptom to appear. It begins close to the onset of the earliest physical symptom (weight gain) and prior to the appearance of other physical manifestations of Cushing's syndrome. Patients describe themselves as feeling overly sensitive, unable to ignore minor irritations, and impatient with or pressured by others. In addition, overreactivity and easy development of anger occur. Patients feel that they are often on the verge of an emotional explosion and that the intensity of anger experienced is also increased.

Depressed mood is reported by 60–80% of patients. There is a range in the intensity of depressed mood. Some patients describe short spells of sadness; others experience feelings of hopelessness and giving up. Suicide attempts are infrequent but may occur. Hypersensitivity and oversentimentality lead to crying spells. For some, crying also occurs as the behavioral response to anger and frustration and feeling unable to respond effectively. Patients also experience spontaneous onset of depressed mood or crying in the absence of any preceding upsetting thought or event.

The time course of the mood disturbances is noteworthy. Most patients report that their mood disturbances are intermittent rather than sustained. Sometimes they wake up depressed and remain depressed throughout the day or the next day as well. Alternatively, the onset of depressed mood and/or crying might occur during the day, often suddenly. The duration of each depressive episode is usually 1 to 2 days and is rarely longer than 3 days at a time. A frequent weekly total is 3 days per week. There is no regular cyclicity, however, so patients cannot predict when a depressive day will occur. Although there are intervals when they might not experience pleasure, these patients do not experience the unrelenting, unremitting inability to experience pleasure that is characteristic of patients with severe psychiatric depressive illness. There are intervals when patients retain the capacity for pleasure, finding enjoyment in hobbies and interpersonal relationships. At times,

they may find it difficult to initiate such activities, although once others mobilize them, they are able to enjoy them. Some patients do experience decreased interest in their environment.

Social withdrawal is less common, but can occur. Sporadic withdrawal might occur because of the patient's need to remove him- or herself from a situation of overstimulation that elicits the fear of impending emotional dyscontrol. Guilt is infrequent; if present, it is not excessive, self-accusatory, or irrational, but is related to remorse about angry outbursts and inability to function well at work and in the family. Hopelessness is infrequent, but, if present, is attributed to the increasing physical and emotional disability that has puzzled the patient's physicians and been resistant to treatment interventions until the diagnosis of Cushing's syndrome is finally made.

A minority of patients experience episodes of elation-hyperactivity early in the course of the illness. These episodes of elation are described as a high. During these episodes, patients are more ambitious than usual and might attempt to do more than their ability and training make reasonable. Increased motor activity is present, with restlessness and rapidly performed activities. Patients report embarrassment that their speech is both loud and rapid. As the illness progresses and new physical signs of Cushing's syndrome begin to appear, this type of episode becomes rare or disappears entirely.

A percentage of patients report generalized anxiety. New-onset panic disorder has also been observed in patients with Cushing's syndrome. In addition, even patients who do not experience psychic anxiety describe episodic symptoms of autonomic activation such as shaking, palpitations, and sweating.

Biological Drives

Abnormalities in four areas of basic biological vegetative drives are present:

1. Fatigue. This is reported by 100% of patients.
2. Libido. A decrease in libido is very frequent and reported by close to 70% of patients. In fact, this is one of the earliest manifestations of Cushing's disease, beginning when the patient is experiencing the first onset of weight gain.
3. Appetite and eating behavior. More than 50% of patients have an alteration in their appetite; in 34% appetite is increased; in 20% it is decreased.
4. Sleep and dreams. Difficulty with sleep, particularly middle insomnia and late insomnia (early morning awakening), is found in more than 80% of patients. Difficulty with early insomnia (not falling

asleep at bedtime) is not as frequent. One-third of patients report an alteration in the frequency or quality of their dreams, which are increased in their frequency and intensity and become bizarre and very vivid. Some patients report they have lost the ability to wake themselves out of a nightmare. Sleep EEG studies indicate that there are many similarities between Cushing's disease patients and patients with major depressive disorder. For example, both groups show significantly less total sleep time, lower sleep efficiency, and shortened rapid eye movement (REM) latency compared to normal subjects.

Cognition

Cognitive symptoms are a prominent part of the clinical picture. Most patients report difficulty with concentration, inattention, distractibility, and shortened attention span. Some patients report episodes of scattered thinking, while others note slow thinking. Thought blocking may occur in more severe instances. Patients may find themselves using incorrect words while speaking or misspelling simple words. Perceptual distortions are very rare.

Impairment of learning and memory is among the most frequent symptoms and is reported by 80% of patients. Patients report problems with registration of new information. They commonly repeat themselves in ongoing conversations. They easily forget items such as appointments made, names of people, and location of objects.

Most patients have no disorientation or overt clouding of consciousness, and their waking electroencephalographs (EEGs) are not characteristic of delirium. On mental status bedside clinical evaluation, difficulties with tests such as mental subtraction and recall of recent U.S. presidents are seen in close to 50% of the patients.

Detailed neuropsychological studies reveal that individuals vary in the severity of degree of cognitive dysfunction, with minimal or moderate to severe decrements in a variety of subtests seen in close to two-thirds of patients. Verbal functions and learning are particularly affected. Once learned, the percent retention of verbal material is not subnormal. The overall pattern of decrements in cognitive function suggests the involvement of both frontal lobe and hippocampus.

Specific Features of the Neuropsychiatric Symptoms

The psychiatric symptoms that develop in Cushing's syndrome are not simply a nonspecific response to

severe physical illness. Irritability and decreased libido occur early, often before patients are aware that they have any physical problems other than weight gain. Later, when depressed mood appears, it is not simply the demoralization seen in the medically ill, but episodic sadness and crying, sometimes occurring in the absence of depressive thought content. The incidence of depressive disorders is greater than in comparison groups with other types of pituitary tumors or hyperthyroidism. Although they have difficulty with concentration and memory, patients with Cushing's syndrome are not delirious.

The overwhelming majority of patients with spontaneous Cushing's syndrome do not have very severe neuropsychiatric disturbances of a psychotic or confusional nature, as patients receiving corticosteroids for treatment of certain physical disorders sometimes may. This can be understood by considering that patients with spontaneous Cushing's syndrome differ from those receiving high-dose steroids in several respects. The level of circulating cortisol in the former is not as high as the equivalent amount of steroid administered to the latter. Patients with Cushing's syndrome also differ from those receiving exogenous steroids in that they are exposed to sustained elevated cortisol levels for months to years and are less subject to sudden acute shifts and rapid rates of change of steroid levels that occur during short-term treatment with high-dose corticosteroids.

Although similar in many respects to the major depressive disorders, the depression seen in Cushing's syndrome does have certain distinguishing clinical characteristics. Irritability is a prominent and consistent feature, as are symptoms of autonomic activation such as shaking, palpitations, and sweating. Depressed affect is often intermittent, with episodes lasting 1 to 3 days and recurring very frequently at irregular intervals. Patients usually feel their best, not their worst, in the morning. Psychomotor retardation, although present in many patients, is usually not so pronounced as to be clinically obvious and is usually apparent only in retrospect after improvement with treatment. The majority of these patients are not withdrawn, monosyllabic, unsponaneous, or hopeless. Their guilt, when present, is not irrational or self-accusatory and is primarily related to their realistic inability to function effectively. Significant cognitive impairment, including disorders of concentration, learning, and memory, is a very consistent and prominent clinical feature.

Improvement in Neuropsychiatric Symptoms after Treatment

Significant improvements in depression rating scores occur after treatment produces decreases in cortisol.

In treated patients, improvements in depressed mood begin with a decrease in the frequency of days when the patient feels depressed. In addition, each episode lasts a shorter period of time, perhaps only a few hours instead of 1 to 2 days. The patients also describe a change in the quality of the depressive mood, so that they no longer experience it being as deep. They no longer feel depressed without some external precipitating reason. A mood change comes on gradually and abates gradually, rather than appearing suddenly as before. Crying becomes less frequent, is less easily elicited by environmental upsets, occurs only with some identifiable external precipitant, and is of shorter duration.

The time course of improvement in depressed mood compared to improvement in other neurovegetative symptoms is of interest. In patients with Cushing's disease who manifest depressed mood at initial evaluation and are subsequently studied during the first 12 months after treatment, improvement in symptoms other than depressed mood occur prior to improvement in depressed mood. Depressed mood is less likely than irritability and sleep, for example, to be among the first cluster of symptoms to improve. Interestingly, this lag is similar to that seen in psychiatric patients with depressive episodes treated with antidepressants, in whom improvements in sleep and psychomotor activity often occur prior to improvement in depressed mood.

Cognitive testing after treatment indicates improvement in many, but not all, affected functions. After cortisol levels decline to normal concentrations, verbal learning and verbal functions such as verbal fluency improve.

Antidepressant medication is more effective after treatment has normalized cortisol levels. When selective serotonin reuptake inhibitors are administered prior to treatment, patients report only partial effectiveness, so that only mood or only vegetative symptoms improve. After treatment, antidepressants can be helpful when depressed mood lingers or is exacerbated by the sharp and rapid decline in steroid levels.

The long-term impact of Cushing's disease on subjective well-being after cure has been studied by using validated health-related questionnaires that assess quality of life. While there is partial resolution of physical and psychosocial decrements after treatment, at long-term follow-up many report some decrease in quality of life.

Brain-Imaging Studies in Cushing's Syndrome

Brain-imaging technology has provided further information about the effects of cortisol on brain structure and function. The hippocampus is a brain

structure key to learning and memory. During active Cushing's syndrome, greater elevations in cortisol are associated with smaller hippocampal formation volume. Reduced hippocampal formation volume is associated with lower scores for verbal learning and recall. After treatment reduces cortisol concentrations to normal, the hippocampal formation increases in volume more consistently and to a greater degree than other brain structures examined for comparison. Greater decreases from the initial pretreatment cortisol levels are associated with greater increases in hippocampal formation volume. Studies indicate that patients with Cushing's disease show a reduction in the metabolism of glucose in several brain regions. Studies using functional brain imaging in Cushing's syndrome indicate altered activation in the verbal learning (encoding) systems, including the hippocampus. In addition, accuracy of emotion processing is decreased, and altered activation patterns occur in the brain regions subserving it.

Mechanisms for the Behavioral Effects of Cortisol

The neuropsychiatric abnormalities seen in untreated Cushing's syndrome are related, at least in part, to the effect of elevated levels of cortisol. Cortisol has pleiotropic effects in the central nervous system. Possible mechanisms for the effect of cortisol on mood, cognition, and vegetative functions include those already shown to be actions of glucocorticoids in animals. These include a direct effect on receptors of central nervous system cells, the synthesis or function of neurotransmitters, effects on glucose metabolism and electrolytes, increasing sensitivity of the brain to other neuroactive substances such as excitatory amino acids, effects on nerve growth factors, and neurogenesis.

While this article has focused on a single adrenal steroid, cortisol, levels of other adrenal glucocorticoids as well as sex steroids produced by the adrenal, such as testosterone and dehydroepiandrosterone (DHEA), are also altered in patients with Cushing's syndrome. These substances likely modify the effect of cortisol on psychopathology, and their role remains to be elucidated.

Relationships between Stress and Immunity
Impact of Stress and Behavior on Cytokine Expression
Impact of Cytokines on Stress and Behavior
Summary

Glossary

<i>Cytokine</i>	Small molecular weight glycopeptide produced by a variety of cell types that serve to modulate immune and inflammatory responses.
<i>Immunoendocrinology</i>	The study of the impact of soluble products of the immune system on endocrine and neuroendocrine networks as part of the bidirectional communication between the immune and endocrine systems.
<i>Psychoneuroimmunology</i>	The study of the relationships between neurocognitive behaviors, neuroendocrine response, and immune changes occurring in response to stress.
<i>Regulatory T cells</i>	CD4+ (and some CD8+) cells that reside in both the central and peripheral immune systems whose main function is to regulate the intensity and duration of immune responses by inhibiting both cytokine production and effector function.
<i>Stress</i>	Perturbation of homeostatic state by environmental factors demanding an adaptive response from the host.
<i>T helper cell</i>	Lymphocyte that plays a central role in immune modulation by selectively activating various immune and nonimmune cells through the production of specific cytokine combinations.

Relationships between Stress and Immunity

Stress Defined

Stress is best thought of as a psychophysiological process, usually experienced as a negative emotional state. Stressors, defined as events with the potential for posing threat, harm, or challenge to the host, are judged in the context of personal and environmental factors, and if appraised as threatening or challenging, initiate specific physiologic responses directed at reducing or eliminating the stress (fight-or-flight). The field of psychoneuroimmunology seeks to establish the link between behavior, neuroendocrine functions, and immune responses.

Impact of Stress on Health

A common clinical observation is the often adverse relationship between stress and human disease. Various sources have estimated that up to 75% of all visits to physicians' offices are stress-related. This appears to be particularly true in relationship to immune-based dysfunction such as increased susceptibility to infections, autoimmune, allergic, and asthmatic diseases. Stress is also suspected to play a role in morbidity and mortality in other immune-based diseases such as cancer, HIV disease, inflammatory bowel diseases, and even aging. Stress may also cause persistent increases in sympathetic nervous system activity, including increased blood pressure, heart rate, and catecholamine secretion, as well as platelet aggregation which may explain, at least in part, the known association between stress, immune alterations, and cardiovascular disease. Emerging evidence suggests that sleep alterations can modulate the stress–health relationship. Acute stressors and adverse naturalistic events are associated with sleep disruptions as measured by self-report and polysomnography. Poor sleep, in turn, is associated with subsequent decrements in mental health including symptom reporting, incident cases of mood and anxiety disorders, and

immune function. Sleep disruptions have also been associated with adverse physical health outcomes, including increased morbidity and mortality compared to populations with adequate patterns and duration of sleep.

Role of Cytokines in the Normal Immune Response

In the normal host, presentation of antigen for a specific protective immune response elicits a complex series of events that results in a mixed cellular and humoral protective response, the intensity and nature of which depends upon the specific inciting antigen. Generally speaking, extracellular parasites (i.e., bacteria) incite primarily a humoral response while intracellular parasites (i.e., virus, fungi, mycobacteria, etc.) elicit a cell-mediated response. Antiviral immunity is particularly complex because both arms are necessary for host resistance – cellular immunity to eliminate the virus-infected host cells and humoral immunity that produces antiviral neutralizing antibodies to prevent reinfection. The host immune response has a variety of mechanisms to direct the immune response into the humoral versus cellular direction, i.e., nature of antigen-presenting cells, major histocompatibility complex (MHC) restriction, and availability of specific T and B cell components. However, the central control of the cellular versus humoral response to an antigenic challenge appears to be via production of specific cytokine milieu.

All cytokines have certain properties in common. They are all small molecular weight peptides or glycopeptides. Many are produced by multiple cell types such as lymphocytes, monocytes/macrophages, mast cells, eosinophils, and even endothelial cells lining blood vessels. Each individual cytokine can have multiple functions depending on the cell that produces it and the target cell(s) on which it acts (called pleiotropism). Also, several different cytokines can have the same biologic function (called redundancy). Physiologically it appears that most cytokines exert their most important effects in a paracrine and/or autocrine rather than endocrine fashion. Their major functions appear to involve host defense or maintenance and repair of the blood elements.

Cytokines are categorized by their major specific function(s) and there are five major categories. Interferons (IFNs) are so named because they interfere with virus replication. There are three major types based upon the source of the IFN. IFN alpha (IFN α) is produced by the buffy coat layer from white blood cells, IFN beta (IFN β) by fibroblasts, and IFN gamma (IFN γ) by activated T cells, natural killer (NK) cells, and dendritic cells (DC). IFN γ is an important immunoregulatory molecule in

determining intracellular versus extracellular host defense responses.

The colony stimulating factors (CSFs) are so named because they support the growth and differentiation of various elements of the bone marrow. Many are named by the specific element they support such as granulocyte colony stimulating factor (G-CSF), macrophage colony stimulating factor (M-CSF), and granulocyte macrophage colony stimulating factor (GM-CSF). Other CSFs include interleukin (IL)-3, which can stimulate a variety of hematopoietic precursors and is being evaluated as a therapy in aplastic anemia and bone marrow transplantation; and c-Kit ligand (stem cell factor) which has been demonstrated as a cytokine necessary to cause the differentiation of bone marrow stem cells into their various precursor elements for eventual differentiation into erythrocytes, white blood cells, and megakaryocytes (platelets).

The tumor necrosis factors (TNFs) are so called because injecting them into animals causes a hemorrhagic necrosis of the animals' tumors. TNF- α is produced by activated macrophages and TNF- β is produced by activated T cells (both T helper (Th) and cytotoxic T lymphocytes (CTL)). These molecules appear to be involved in the pathogenesis of septic shock and much research is aimed at trying to inhibit their activity in septic patients.

The newest group described is the chemokines, small molecular weight proteins that promote chemotaxis and activation of cells to tissue sites experiencing inflammatory reactions. Currently more than 50 human chemokines and 18 receptors have been identified. They appear to be intimately involved in generating selective types of inflammatory cell infiltrates both because of the specific chemokine milieu produced as well as selective expression of particular chemokine receptors on specific inflammatory cell subpopulations. They are categorized into subfamilies (CXC, CC, CX3C, and so on) based on their chemical composition of N-terminal cysteinyl receptors. Examples include RANTES (regulated upon activation, normal T cell expressed and secreted), macrophage inhibitory peptide (MIPs), and eotaxin.

The largest group is the ILs, so named because their fundamental function appears to be communication between (inter-) various populations of white blood cells (leukocytes – leikin). They are produced by a variety of cell types such as monocytes/macrophages, T cells, B cells, and even nonleukocytes such as epithelial cells.

A central source of these cytokines comes from CD4+ helper T cell subpopulations, often referred to as Th1 and Th2 cells. Human Th1 cells secrete a specific cytokine profile including IFN γ and TNF- β .

These cytokines are important helper factors in the generation of cellular immune responses including antigen-specific CTL and NK cells. Additionally, IFN γ in particular has an antagonistic activity against Th2 cytokines. IL-12, produced primarily by activated macrophages and other antigen presenting cells (APC), plays a central role in inducing IFN γ production. In contrast, Th2 cells secrete IL-4, IL-5, IL-9, IL-10, and IL-13, which are involved in isotype switching of B cells as well as proliferation and differentiation into antibody-secreting plasma cells. In particular, IL-4 and IL-13 are involved in the isotype switch from immunoglobulin (Ig)M to immunoglobulin (Ig)E, the antibody responsible for classical allergic disease. IL-4 and IL-10 are also regulatory cytokines, antagonizing the activities of Th1 cytokines. In humans, Th cells can have a third cytokine secretory pattern. Th0 cells are capable of secreting all of the above mentioned cytokines and are often thought of as precursors that differentiate into the Th1 or Th2 pathway with antigen challenge. Thus it can be said that the nature, intensity, and duration of a specific immune response depends upon the delicate balance between Th1 and Th2 numbers and/or activities. Since it is now appreciated that many other cell types besides Th cells produce IFN γ , IL-4, IL-5, IL-9, and IL-10, many scientists now refer to these as type 1 and type 2 cytokines, supporting cellular and humoral immune responses, respectively.

Impact of Stress on Neuroendocrine and Immune Function

Extensive research efforts have also examined various psychosocial variables in order to predict patterns of adjustment to stressful situations. These variables include optimism, social support, and coping responses, all of which have been found to buffer the psychological, cardiovascular, endocrine, and immune effects of stress and predict overall adjustment to stressful life events. Further, social support and coping strategies can moderate these effects. There is also research indicating that coping style mediates the effects of social support on distress, such that patients who receive social support may use fewer avoidance coping strategies and therefore have lower overall distress. Similarly, in addition to the direct effects optimism has on adjustment to stressful situations, some researchers have found that the benefits of an optimistic disposition are mediated through its effects on both social support and coping responses. These data lend support to the notion that many of these immune imbalances can be reversed with various forms of stress management.

Impact of Stress and Behavior on Cytokine Expression

It has been suggested that acute versus chronic stress may exert distinct effects on host immunity. Acute stress may initially produce an adaptive immune response that is actually protective of the normal host. NK cell activity, as well as certain potentially antiviral cytokines, increases in normal individuals who undergo acute laboratory stressors. Interestingly, chronic stress exposure appears to result in the opposite effect with decreases in NK function and antiviral cytokines. It has also been reported that acute psychological and/or physiological stresses can be associated with adverse clinical outcomes. It is plausible that chronic stress disrupts the ability of some individuals to generate a protective homeostatic immune response when faced with acute stressful events.

Inflammatory Cytokines

When the host is subjected to infection, trauma, or injury, a series of cellular and molecular events occur to defend against potential invading organisms and initiate tissue repair. Collectively, these events are called inflammation and are of central importance in the maintenance of homeostasis. The normal components of inflammation involve the production of a variety of cytokines that function to recruit and activate the cellular components of inflammation and tissue repair which include neutrophils, mast cells, macrophages, and fibroblasts. This cellular cascade can be initiated by local microbial invasion through production of substances such as endotoxin (lipopolysaccharide – LPS) or the host neuroendocrine system with production of molecules such as substance P. Acute inflammation is characterized by the recruitment of polymorphonuclear (PMN) cells, basophils/mast cells, and the production of fibrinogen to aid in hemostasis. If the inflammatory response continues and becomes chronic, the PMN cells are replaced by mononuclear cells such as lymphocytes and monocytes/macrophages.

Stimulation of neurons can cause localized release of substance P which results in tissue edema from peripheral vasodilatation. Substance P can also stimulate tissue mast cells to become activated and release preformed histamine and other chemical mediators of inflammation including cytokines such as IL-4 and GM-CSF. Augmenting the response, histamine can bind to H1 and H2 receptors located on sensory nerve bodies and axons, further stimulating the release of substance P and thus potentiating the inflammatory reaction.

The major inflammatory cytokines are often considered to be TNF- α , IL-1 β , and IL-6. This is accompanied by the production of hepatic proteins collectively known as acute phase reactants (APR) that function to limit the activity and spread of invading microorganisms. Studies have shown the increase in serum inflammatory cytokine levels with certain types of acute stress likely due to mononuclear phagocyte activation. Epinephrine has a similar effect on increasing inflammatory cytokine production *in vitro* and is known to be increased *in situ* during acute stressful events. Acute stress also causes the increased production of substance P which appears to promote upregulation of many cytokines including the primary inflammatory TNF- α and IL-1 β . The substance P effect may be direct through stimulation of mononuclear cells or indirect through the induction of increased adrenal catecholamine secretion with stress.

Chronic stress is usually associated with diminished inflammatory response and poor wound healing. The inflammatory cytokine-APR networks can be inhibited by corticosteroids. Chronic stress, through the activation of the hypothalamic-pituitary-adrenocortical (HPA) axis, can increase systemic cortisol levels, thus acting as an inhibitor of inflammation. The increase in inhibitory cytokines, especially IL-10, which accompanies chronic stress may also contribute to the anti-inflammatory activity of stress.

Finally, in certain inflammatory diseases, there appears to be a paradoxical response to chronic stress that results in exacerbation of inflammatory pathways. While the mechanisms have not been established, it appears to involve more the systemic imbalance between pro- and anti-inflammatory cytokines rather than the absolute levels of any specific cytokine. Further, therapeutic interventions for stress reduction have demonstrated a salutary clinical effect in subpopulations of patients identified as having high stress levels. Work is in progress to determine whether this correlates with changes in any cytokine levels.

Immunoregulatory Cytokines

Recent work has demonstrated that the examination of only a single component of an immune response can lead to inaccurate conclusions regarding immunosuppression versus dysregulation. The reporting of a Th1/Th2 cytokine network subsequently expanded to include other cytokine-producing cells helps to explain the observations that an inappropriate humoral response to an antigen that requires a cellular response (and vice versa) is as harmful to the host as is generalized immunosuppression. Cytokines

can function in an immunoregulatory fashion, both by upregulating and downregulating the overall immune response as well as directing it toward a cellular, humoral, or mixed response. This is in response to antigen-presenting cells directing a host response to be primarily cellular or humoral against an intracellular versus extracellular parasite invasion.

Stress has been reported to have distinct effects on immunoregulatory cytokine production. A fundamental cytokine for expansion of an ongoing immune response is IL-2. Corticosteroids decrease IL-2 production by T cells. Investigations using rodent models have shown that IL-2 levels and production capability are decreased with various forms of stress. The continuance of diminished IL-2 is observed in adrenalectomized animals and indicates the complex nature of this phenomenon. Similar observations have been made for IFN γ . In rodents, IL-2 and IFN γ are produced by Th1 cells while IL-4, IL-5, and IL-10 are produced by Th2 cells. Several studies in animal and humans have shown the decrease in Th1 (type 1) cytokines with a concomitant rise in Th2 (type 2) cytokines in stress models such as chronic restraint, medical student exams, major depressive disorders, and chronic pain.

In contrast, acute stress in normal animals and humans has been reported to cause at least a transient increase in NK cell activity accompanied by increased IFN γ and decreased IL-10 production. This may represent an innate host immune response for protection against intracellular parasites similar to the demargination of granulocytes for host defense against extracellular parasites in the peripheral blood observed with acute stress. Some studies report that the changes in type 1/type 2 cytokine production are different with acute stress superimposed on a chronically stressed host. This could, at least in part, explain the observations of increased susceptibility to and durations of infections, particularly viral, observed in chronically stressed individuals.

Effector Cytokine Networks

Aside from inflammatory and immunoregulatory activities, cytokines also have direct effector functions. These functions include thermoregulation, antiviral, cytotoxic, and cell trafficking. IL-1, IL-6, and TNF- α have all been described as endogenous pyrogens and function to alter the core temperature as a host defense against invading microorganisms. Antipyretic drugs decrease the sensitivity of the hypothalamus to the effects of these cytokines. IFN γ can have a direct antiviral IFN effect. It also activates macrophages to increase antigen processing of viral particles and CTL and NK cells to kill virally infected

target cells. CTL make TNF- β (lymphotoxin) in response to specific antigen challenge that can directly kill the target cell. In order for a host immune response to be protective, the elements of the response must reach and remain at the site of the invading microorganism. This occurs primarily with alterations in leukocyte trafficking through the production of chemokines and adhesion molecules. Specific combinations are critical to insure the proper type, sequence, and duration of inflammatory cell influx.

The effects of stress on these effector networks have not been extensively investigated. Body temperature in situations of acute stress has been reported to increase in both humans and animal models. No significant long-term changes have been reported with chronic stress. As IFN γ levels decrease with chronic stress, it is not surprising that increased incidence, duration, and susceptibility to viral infections occur in these affected populations. This may be the result of decreased CTL and NK cell activity seen with chronic stress. Adhesion molecule expression on lymphocytes and target tissue cells as well as chemokine secretion are both inhibited by glucocorticoids and thus could be expected to diminish in stress environments where HPA axis activity is high.

Impact of Cytokines on Stress and Behavior

It has been appreciated for some time that cytokines can have a direct effect on the central nervous system (CNS) and thus psychological components of the host. This can occur directly through effects on certain parts of the brain that control behavior directly (i.e., hippocampus) or indirectly through the neuroendocrine network involving the hypophyseal-pituitary-adrenal axis. The end result is that cytokine production can affect behavior in both positive and negative ways for host homeostasis.

Effects of Cytokines on the Central Nervous System

This area is only recently emerging as a field of study. Much impetus for study has been as a result of the increased use of recombinant cytokines for the treatment of a variety of diseases. The CNS side effects observed with these agents has led to speculation as to the components of the CNS most affected. Although there is evidence to suggest that recombinant cytokines do not directly cross the blood-brain barrier (BBB), the relationships are none-the-less clear. The patterns with the cytokines are remarkably similar: an acute toxicity (flu-like illness) followed by chronic phase (neuras-thenia) with continued cytokine administration. The

nature and severity of the chronic symptoms appear to be dose related but occur virtually with all regimens given for more than 2 months. More severe symptoms such as psychomotor and cognitive disorders as well as delirium and coma may develop at any point in the therapeutic regimen and appear to be related to underlying CNS dysfunction (aging, history of brain injury, and concomitant CNS disease).

Natural and recombinant IFNs (α , β , and γ), T cell growth factors (IL-2, IL-4, and IL-12), proinflammatory cytokines (IL-1, IL-6, and TNF- α), and hematopoietins (GM-CSF, IL-3, and stem cell factor) have all been utilized to treat patients with a variety of illnesses. Their biochemistry and receptor bindings are largely unique yet all share similar CNS toxicities suggesting mechanisms based upon common albeit as yet undescribed physiologic activities.

Another area of research that suggests a direct effect of cytokines on CNS activity is pain perception in areas of inflammation. Pain is a protective host response generated in answer to tissue injury. It is mediated by afferent sensory nerves in the midst of tissue injury producing enhanced sensitivity to further noxious (hyperesthesia) as well as innocuous (allodynia) stimuli. The peripheral sensory nerve releases substance P into the injured area which in turn can modulate the production and secretion of inflammatory cytokines (such as TNF- α and IL-1) from resident inflammatory cells which promote the pain response. The effect appears to be indirect through production of nerve growth factor, prostaglandins, etc., since no cytokine receptors have been demonstrated on peripheral nerve cells.

Pain control in peripheral as well as CNS tissue involves endogenous opiate receptors. Corticotropin-releasing hormone (CRH) is part of the HPA axis upregulated in stress responses. It also upregulates the secretion of endogenous opiate precursors in both peripheral and central nervous tissues. IL-1 can potentiate the CRH response. Of note, both IL-1 and CRH receptors are present on lymphocytes and are upregulated during inflammation. Binding of either IL-1 or CRH causes these lymphocytes to secrete β -endorphins. Although IL-1 can mediate hyperesthesia in normal tissue, it appears that IL-1, through upregulation of CRH receptors, can mediate analgesia through inducing the local production of β -endorphin by lymphocytes.

Effects of Cytokines on Neuroendocrine Networks

The effect of HPA as well as sympathetic adrenal medullary (SAM) hormones on immune function has been extensively studied. Much work has been done to characterize the effects of various cytokines

on neuroendocrine networks to further define the bidirectional communication between neuroendocrine and immune systems. Research to date strongly suggests that the mechanism for this bidirectional crosstalk involve shared ligands and receptors. While stress is known to effect immunity primarily through its effect on neuroendocrine networks, stimulation of the immune system by invading microorganisms produce a cytokine milieu that can have a direct effect on the neuroendocrine network through CNS receptor binding.

There are multiple neuroendocrine hormones produced by components of the immune system including adrenocorticotrophic hormone (ACTH), CRH, thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin (PRL), growth hormone (GH), and somatostatin (SOM). This explains the observation of various immune activations (including cytokine production) noted *in vitro* after incubation of immune cells with these hormones. The exact physiologic role of these immune cell-derived neuropeptides is still not established.

However, when a microorganism invades the host, immune activation leads to cytokine production that finds its way to the BBB via the peripheral circulation. The cytokines do not pass but bind to neuronal cells in the hypothalamus via their specific cytokine receptors. Although there are many different possible cytokine combinations that may bind CNS tissue, common neuroendocrine effects include upregulation of ACTH and downregulation of TSH release. IL-1, IL-2, IL-6, and TNF- α all activate the adrenal axis through the stimulation CRH and/or ACTH directly. IL-1 and TNF- α inhibit the gonadal axis through downregulation of luteinizing hormone-releasing hormone (LHRH). TNF- α and IFN γ can both inhibit the thyroid axis through downregulating thyrotropin-releasing factor (TRF).

Effects of Cytokines on Behavior

Neurocognitive defects with various cytokines have been described in many of the studies using recombinant cytokine therapy. Further, somnolence, psychoses, depression, and personality changes have all been reported during and after cytokine infusions. Yet it is the so-called sickness behavior (malaise, social withdrawal, somnolence, and hyperesthesia) associated with cytokine release after infection, trauma, or even stress that best demonstrates the effects of cytokines on behavior.

Another condition implicating the relationship between cytokines and behavior is depression. Major depressive disorders commonly occur after

stressful episodes and are associated with increased HPA hormone levels. Interestingly, cardinal clinical symptoms of depression (somnolence, anorexia, and diminished libido) can all be induced by cytokines. IL-1, TNF- α , and IFN γ are all soporific when administered systemically. Anorexia is a major clinical sign in both depression and infections. TNF- α , IL-1, and IL6 have all been reported to suppress appetite in both animal models and humans receiving recombinant cytokine therapies. Libido requires an intact hypophysial-pituitary activity to stimulate production of sex hormones. These can also be regulated by the inflammatory cytokines noted above. Of note, several studies report increased IL-1 and IL-6 levels with decreased IL-2 and IFN γ in plasmas from depressed patients.

Summary

The relationships between stress, distress, immunity, and health are now generally accepted but still not fully defined. Cytokines play a central role in immune responses and are quite sensitive to the effects of both acute and chronic stress through the neuroendocrine network. This can be both a physiological protective system as well as pathologically imbalanced or suppressed. Many factors influence the balance between cytokine and neuroendocrine networks and impact host defense mechanisms against infection, hypersensitivity diseases, and cancer. The stressors that influence host defense can be psychological, physiological, or a combination. Cytokines can, in turn, influence neuroendocrine networks, CNS function, and even behavior directly. A better understanding of the cytokine–neuroendocrine crosstalk and the influence of various stressors on that crosstalk offers opportunity for future interventional strategies for stress-related illnesses.

Glossary

Cancer-related fatigue A persistent feeling of tiredness, weakness, or lack of energy related to cancer and/or its treatment; it is more severe than general fatigue and interferes with regular functioning and quality of life.

Chronic fatigue syndrome (CFS) A complex syndrome of unknown etiology marked by persistent fatigue that lasts for over 6 months and interferes with daily functioning.

C-reactive protein (CRP) An acute-phase protein that is produced by the liver during inflammation. CRP increases in response to the cytokine interleukin-6. Elevated CRP levels are currently considered the strongest prognostic indicator of increased risk for stroke as well as for myocardial infarction and

	death from coronary events. Recent studies indicate that elevated CRP is associated with cognitive decline.
<i>Cytokines</i>	A diverse group of potent, low-molecular-weight proteins and glycoproteins that mediate important physiological processes within the immune system as well as the nervous and endocrine systems. Major types of cytokines include the interleukins (ILs), tumor necrosis factors (TNF), and interferons (IFNs).
<i>Fatigue</i>	A persistent feeling of tiredness, weakness, or lack of energy. There are many components of fatigue, including physiological (such as flulike symptoms and anemia), psychological (including depression), cognitive (including memory and attention problems), and chronological (such as circadian rhythms disorders and sleep disruption).
<i>Multiple sclerosis (MS)</i>	An autoimmune disorder characterized by the degeneration of myelin in the central nervous system, leading to muscle weakness, cognitive disorientation, and fatigue.
<i>Soluble cytokine receptors</i>	Biologically active receptors that circulate in the extracellular matrix. Soluble cytokine receptors may function as antagonists (i.e., inhibiting the effects of a cytokine by binding to it and blocking it from attaching to its cell-bound receptor) or agonists (i.e., promoting the effects of a cytokine by binding to it and forming a complex that binds to a different receptor subunit that initiates signal transduction).
<i>Vascular endothelial growth factor (VEGF)</i>	An important cytokine that is produced by the endothelial cells. It is an angiogenic cytokine, meaning it supports the formation of new blood vessels, including those for tumors.
<i>Vital exhaustion</i>	A syndrome marked by persistent fatigue, often stemming from an inability to cope with one or more chronic stressors, and implicated as an independent risk factor for negative cardiovascular events.

Cytokines: Description and Classification

Description

Cytokines are potent immunotransmitters that play a pivotal role in immune system response and communication with other physiological systems, both to maintain homeostasis and to respond appropriately to infection and injury. The functions of cytokines are diverse: They assist in the development and

proliferation of immune cell subsets, promotion of inflammatory as well as noninflammatory processes, and alteration of neurochemical and neuroendocrine processes that affect overall physiology and behavior. Cytokines may be thought of as similar to neurotransmitters and hormones in that they are mediators of specific physiological responses, rely on receptor-ligand interactions, and have self (autocrine), local (paracrine), and distal (endocrine) effects.

In addition to their multiple effects within the immune system, cytokines also have extensive bidirectional communication with the central nervous system (CNS) and hypothalamic-pituitary-adrenal (HPA) axis. Probably due to this communication, cytokines are correlated with a number of psychological states, including chronic stress and fatigue.

Classification

There are major families of cytokines. The interleukins (ILs) are a large class of cytokines that promote cell-to-cell interactions and the stimulation of humoral or cell-mediated immune responses. The tumor necrosis factors (TNFs) include a host of cytokines characterized by several molecules, such as TNF- α and TNF- β and soluble TNF receptor-I (sTNFRI) and TNF receptor-II (sTNFRII). The activation of the TNF family promotes a variety of cell functions related to inflammation as well as immune organ development and maintenance, including cell proliferation and adhesion, cell differentiation, apoptosis, and cell survival. The interferons (IFNs) play an important role immunosurveillance, antiviral, and antitumor effects. IFN- α and IFN- β inhibit virus replication in infected cells, and IFN- γ stimulates major histocompatibility complex (MHC) presentation on antigen-presenting cells, aiding in the recognition and lysing of foreign cells. In addition, IFNs initiate cascades of cytokine responses, which result in a further immune activation.

Soluble receptors of cytokines are formed either by the cleavage of portions of transmembrane protein complexes, thereby becoming part of the extracellular matrix, or by translation from alternatively spliced mRNAs. They can serve as both antagonists or agonists. Examples of soluble cytokine antagonists include IL-1 receptor antagonist (IL-1Ra) and TNFRI receptor antagonist. Examples of soluble cytokine agonists include IL-6 receptor (IL-6R). In certain situations, some cytokine receptors may function as agonists or antagonists, depending on their isoforms (e.g., TNFRII).

Because of their notable variability in structure and function, there have been many attempts to classify cytokines. A classification system that has

proven useful for stress and behavioral medicine researchers is the classification of cytokines as either pro-inflammatory or anti-inflammatory. Pro-inflammatory cytokines, which include IL-1, IL-2, IL-6, TNF- α , and IFN- γ , promote a variety of cell functions that stimulate and enhance inflammation through various methods, including promoting the differentiation of cytotoxic T cells, enhancing increased vascular permeability and cellular adhesion and migration to tissues, and stimulating the release of acute-phase proteins from the liver. These inflammatory immune responses are often described as T-helper-1 (Th1) responses, referring to the T-helper cell subset that generally produces cytokines that initiate inflammatory processes.

Anti-inflammatory cytokines, which include IL-3, IL-4, IL-5, IL-10, and IL-13, are sometimes described as immunosuppressors due to their ability to inhibit the Th1-mediated inflammatory response (often via direct antagonism of Th1-secreted inflammatory cytokines). However, these cytokines themselves promote certain increases in immune response, most notably increased overall production of antibodies and increased eosinophil and mast cell production. Often called the T-helper-2 (Th2) response, these cascades of cytokine-induced immune activation support allergic reactions. It is important to note that some cytokines support both pro- and anti-inflammatory effects depending on the situation (e.g., IL-6 and IL-8), thus rendering the nomenclature of cytokines as either pro-inflammatory or anti-inflammatory less than perfect. IL-6 is also classified as a myokine because it is produced by contracting skeletal muscle and plays an important role in the anti-inflammatory effects of acute exercise.

Cytokines: Central Nervous System and Endocrine Interactions

Cytokines and the Central Nervous System

It is well understood that cytokines are secreted by certain classes of brain cells, including microglial cells and astrocytes. The endogenous expression of cytokines and their receptors have been found in the hypothalamus, basal ganglia, cerebellum, circumventricular sites, and brain-stem nuclei. Included in the considerably large list of brain-active cytokines are IFN- α and IFN- γ ; TNF- α and TNF- β ; and IL-1, -2, -3, -4, -5, -6, -8, -10, and -12. Studies involving the systematic administration of cytokines in some of the brain regions previously mentioned indicate that cytokines promote the release of neurotransmitters, including norepinephrine, dopamine, and serotonin. Thus, in addition to their immunoprotective effects

(such as the regulation of infiltrating leukocytes during times of infection) within the brain, cytokines may promote neurochemical cascades that directly affect mood and behavior. In addition, elevated pro-inflammatory cytokines may also be associated with neurodegenerative disorders; for example, increased IL-6, TNF- α , and IL-1 β have been found in patients with Parkinson's disease.

Cytokines also affect the CNS via peripheral mechanisms. Although cytokines are too large to effectively cross the blood-brain barrier, there are several posited indirect mechanisms of action. One hypothesis is that cytokines enter the brain via passive transport in areas where the blood-brain barrier is not present (e.g., circumventricular sites). Another is that cytokines might bind to cerebral vascular endothelium, facilitating the release of active second messengers such as nitric oxide. Yet another hypothesis is that cytokines might be transported across the blood-brain-barrier via carrier-mediated transport. Finally, it has been posited that cytokines might affect the CNS indirectly via the stimulation of peripheral afferent nerve terminals, via the vagus.

Cytokines and the Hypothalamic-Pituitary-Adrenal Axis

The HPA is part of the neuroendocrine system that is responsible for the cortical as well as adrenal release of hormones in response to stress. Considerable progress has been made in understanding the complex interactions between cytokines and the HPA. Briefly, it is now well understood that complex and dynamic interactive communication exists between cytokines and the HPA and that the regulation of cytokine release, as well as HPA responses to immune insults, are governed in part by positive and negative feedback loops between the two systems. In particular, pro-inflammatory cytokines have been shown to stimulate HPA stress responses, whereas Th2 cytokines can inhibit this activation. For example, pro-inflammatory cytokines appear to activate corticotropin releasing hormone (CRH) and arginine vasopressin neurons in the parvocellular paraventricular nucleus within the hypothalamus. This activation results in a downstream HPA cascade in which CRH is released from the hypothalamus, promoting the release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland and resulting in release of the glucocorticoids corticosterone and cortisol from the adrenal cortex. There are several postulated mechanisms of action for how this cascade is initiated by pro-inflammatory cytokines, some of which involve mediating effects of cytokines on the HPA via afferent vagal fiber activity.

In addition to their effects on the anterior pituitary and adrenal cortex via CRH release from the hypothalamus, pro-inflammatory cytokines may also affect the anterior pituitary and adrenal cortex directly, resulting in similar end-organ effects (release of corticosterone from the adrenal cortex). For example, IL-6 is synthesized and released within the human adrenal gland itself, promoting glucocorticoid release. The multitude of sites of action allows pro-inflammatory cytokines several pathways of promoting a similar end-organ response so that even if higher-level actions of cytokines on hypothalamic or anterior pituitary structures are inhibited (e.g., via antagonism by a Th2 cytokine such as IL-10), some level of glucocorticoid release into the circulation is preserved. In turn, glucocorticoid actions on cytokines help to maintain homeostasis via negative feedback loops. For example, cortisol inhibits cellular synthesis and release of pro-inflammatory cytokines, thus acting to preserve homeostasis in the system. However, the effects of glucocorticoids on maintaining this homeostasis are dampened in cases of chronic stress, possibly due to the ability of the pro-inflammatory cytokines to promote receptor desensitization, downregulation, or prevalence of negative isoforms of the glucocorticoid receptor, causing decreased glucocorticoid sensitivity or glucocorticoid resistance. Thus, cytokines are intimately intertwined with HPA responses, providing a potent influence on stress responses and appearing to play a very active role in HPA modulations during chronic stress and fatigue.

Cytokine Measurement

When we examine cytokines in biological fluids, there are two broad categories for methods of measurement. Immunoassays measure the prevalence of cytokines or their soluble receptors by using either radioisotope-tagged antibodies (i.e., radioimmunoassays, RIAs), or enzyme-linked antibodies (i.e., enzyme-linked immunosorbent assays, ELISAs) that are specific for certain peptides that are part of the cytokine structure. The strengths of immunoassays in general are their ease of use and relatively low cost, combined with a relatively high specificity due to the use of monoclonal antibodies. However, these methods are not immune to methodological problems, and they do not provide information on functionality of the cytokine. Bioassays measure cytokine functionality as indexed by specific biological responses such as chemotaxis (movement through a chemical diffusion gradient), proliferation (increase in numbers of the particular cell line), cytotoxicity (ability of cells to kill pathogens), expression of cell surface molecules, or subsequent release of specific proteins. Bioassays

thus give the researcher information not simply about soluble cytokine levels, but also about some aspect of their functionality. Although they are very sensitive tests, they are generally less specific, less reliable, and more time-consuming than immunoassays.

Other, newer methods also exist for examining whole cells' capacities to produce and release cytokines. Two such notable methods are flow cytometry and enzyme-linked immunospot (ELISPOT), which measure the abilities of single cells to produce or release cytokines, respectively. Most studies discussed in this article relied on ELISA methods for measuring basal (resting) levels of circulating cytokines in peripheral blood, although some studies examined cytokines after stimulating immune cells with a mitogen known to enhance cytokine release (e.g., lipopolysaccharide, LPS).

Cytokines and Chronic Stress

A few studies have examined the effects of chronic stressors on cytokines in humans. Most studies have been conducted with Alzheimer caregivers and the diagnosis of vital exhaustion. Interestingly, chronic stress appears to be associated with immunosuppression in Alzheimer caregivers but associated with pro-inflammatory activity in vital exhaustion.

Chronic Stress Studies with Alzheimer's Disease Caregivers

An early study examining chronic stress and wound healing in Alzheimer caregivers compared to matched controls showed a decrease in IL-1 mRNA secretion in response to LPS stimulation of peripheral blood leukocytes in Alzheimer's caregivers. Significantly, this may have contributed to slower wound healing in this group. Another study reported lower IL-1 β and IL-2 responses to virus-specific stimulation for Alzheimer caregivers than for controls. Alzheimer caregivers have also shown increased intracellular IL-10 (but no change in INF- γ or IL-2) levels in T-helper and T-cytotoxic cells compared to controls, with the difference between these groups being significantly greater for younger subjects. A recent longitudinal study, in which IL-6 levels for Alzheimer's caregivers and controls were tracked over 6 years, showed an almost fourfold rate of increase of IL-6 levels in Alzheimer's caregivers compared to matched controls. This result was consistent even for caregivers whose spouses had died during the 6-year period. Another study examining IL-6 associations with aging and chronic stress in women indicated that Alzheimer's caregivers showed significantly higher levels of IL-6 compared to age-matched women who were experiencing moderate forms of

stress (i.e., moving), as well as compared to older and younger control subjects. These findings suggest that chronic stress associated with Alzheimer's caregiving in the elderly promotes increases in Th2 cytokines and the inhibition of Th1 cytokines. The findings also suggest pathways by which caregiving in the elderly leads to significantly increased risk for deleterious health outcomes even well after the death of the spouse being cared for.

Chronic Stress Studies with Vital Exhaustion

Vital exhaustion has been implicated as an independent risk factor for negative cardiovascular events, such as first stroke and myocardial infarction. Vital exhaustion in women has been linked to elevated circulating TNF- α levels. A study comparing vitally exhausted middle-age males with controls indicated that vital exhaustion was associated with increased levels of IL-6, IL-1Ra, and IL-10 levels, as well as increased procoagulant activity. Similarly, a recent study examining vital versus nonvital exhaustion in male industrial workers showed decreased glucocorticoid sensitivity for highly exhausted men, both by dexamethasone inhibition of LPS-stimulated IL-6 release and by the median inhibitory concentration (IC₅₀; a measure of glucocorticoid sensitivity that is independent of absolute cytokine release). In addition, vitally exhausted workers showed significantly increased resting levels of CRP. Together, the findings suggest that chronic stress-related fatigue in otherwise healthy women and men may be associated with a shift toward a pro-inflammatory profile. These findings are important because they point to some of the linkages between stress-related fatigue in vital exhaustion and the risk of coronary events. Longitudinal studies in this area are needed to elucidate the direction of relationship between elevations in pro-inflammatory cytokines and vital exhaustion.

Cytokines and Fatigue in Clinical Disorders

As already indicated, cytokines have been shown to be associated with fatigue in otherwise healthy individuals. However, alterations in cytokines have also been examined in the context of several clinical disorders marked by persistent fatigue, such as cancer, chronic fatigue syndrome, and multiple sclerosis.

Cytokines and Fatigue in Cancer

Fatigue is one of the most frequent complaints of cancer patients, with studies showing 40–75% of patients reporting feeling tired and weak, and with rates up to 95% during chemotherapy and/or

radiotherapy treatment. Much of the fatigue that cancer patients experience is probably attributable to cytokines that are elevated either by the cellular damage from the cancer itself or by its treatment. Although high levels of certain endogenous cytokines (e.g., TNF- α) are associated with tumor genesis and growth, paradoxically, the exogenous administration of pro-inflammatory cytokines attenuate cancer growth and thus are often used in cancer treatment. This exogenous administration of cytokines for the treatment of cancer often elicits sickness behavior, a syndrome characterized by flulike symptoms including fatigue and depression. In addition, treatments such as chemotherapy and radiation therapy are associated with elevations in pro-inflammatory cytokines (such as IL-1Ra, IL-6, and TNF- α), which, in turn, are associated with elevations in fatigue. We have shown that circulating levels of VEGF are elevated in response to chemotherapy for breast cancer and that these elevated levels are associated with the significantly increased feelings of fatigue and poorer quality of life that result from chemotherapy. Elevations in cytokines may also persist along with fatigue well after treatment. For example, significantly higher serum levels of IL-1Ra and sTNFR_{II} have been found among breast cancer survivors who report a high level of fatigue compared to low-fatigue breast cancer patients, independent of depression.

In addition, sleep loss, a common correlate of fatigue, is associated with elevations in pro-inflammatory cytokines. For example, pro-inflammatory cytokines such as IL-6 and TNF- α are fatigue-inducing cytokines that are elevated during the day in disorders of excessive daytime sleepiness and in healthy subjects following sleep deprivation. Thus, evidence for the interaction between cytokines and cancer-related fatigue suggests that higher levels of endogenous or exogenous pro-inflammatory cytokines predict higher fatigue. However, higher levels of fatigue pretreatment may predict poorer outcomes related to treatment as well. For example, our group has found that breast cancer patients with high fatigue prior to chemotherapy experience poorer sleep in response to chemotherapy (both subjectively and objectively) compared to those with lower fatigue prior to chemotherapy. Whether these alterations in sleep patterns for high-fatigue patients are associated with alterations in cytokine responses to chemotherapy remains to be elucidated.

Cytokines and Fatigue in Multiple Sclerosis

The immune profile of multiple sclerosis (MS) appears to be characterized by self-reactive T cells, as well as an relative elevation in pro-inflammatory

or Th1 cytokines such as IL-2, TNF- α , and IFN- γ compared to anti-inflammatory cytokines such as IL-4 and IL-10. Fatigue is a common complaint in MS, with over one-third of patients reporting significant fatigue. Although the specific etiology of fatigue in these patients remains to be completely understood, a few studies have reported significant associations with fatigue and IL-1 and TNF- α in MS patients. One study has also reported positive associations with CRP and fatigue in MS patients. Several studies have also related fatigue to HPA axis dysregulation. Most studies have reported HPA axis hyperactivity in MS, with a handful of studies reporting significant associations with HPA axis hyperactivity and fatigue. Many researchers in this field suggest that a potential mechanism of fatigue in MS patients stems from elevations in pro-inflammatory cytokines (such as IL-1 and IL-6), which impair in glucocorticoid receptor signaling, driving HPA axis hyperreactivity, which leads to feelings of fatigue. However, this theory remains to be tested.

Cytokines and Fatigue in Chronic Fatigue Syndrome

The immune profile in CFS is complex and mechanisms that are linked to the particular experience of fatigue in these patients are yet to be understood. Common symptoms in CFS include decreased natural killer (NK) cell cytotoxic activity and lymphocyte proliferation, and increased allergic and autoimmune activities. Such a profile is consistent with a relative elevation in Th2 versus Th1 cellular activity; however, findings in the literature cannot yet confirm this contention. For example, findings on basal cytokine levels have been mixed; whereas several studies report elevations in IL-1 α and IL-1 β for CFS patients versus controls, a similar number of studies have reported no differences. Similar equivocal results have been reported for levels in TNF- α , TNF- β , IL-6, and IL-2 for CFS patients versus controls, and findings on HPA dysregulation are also mixed. Heterogeneity in findings is probably due to study differences in methodology as well as the ranges of patient symptoms and comorbidities studied.

With respect to fatigue ratings and cytokines in CFS, very little work has systematically looked at the relations between fatigue ratings and circulating cytokine levels. However, a recent study reports significant associations with fatigue ratings and LPS-stimulated levels of TNF- α and IL-6 compared to control subjects, who showed significant associations with fatigue and stimulated levels of IL-6 but not of TNF- α .

Cytokines and Fatigue in Clinical Disorders: Summary

Studies examining the relation of cytokines and fatigue in clinical populations are burgeoning, with more studies needed to confirm the preliminary results. However, a common thread in studies with cancer, MS, and CFS appears to be a consistent association with pro-inflammatory cytokines with reports of fatigue in these patients. However, the immunological profile in each of these disorders is quite complex, and future studies will need to be more specific in their assessment of disease stage/severity as well as other potential covariates (including depression) before these preliminary results can be confirmed.

In addition, given the preliminary findings on HPA dysregulation and fatigue, as well as the close interaction of cytokines with the HPA axis, future studies should examine in detail the interactions with potential elevations in pro-inflammatory cytokines and glucocorticoid sensitivity. The use of structural equation modeling methods combined with a careful assessment of data should shed light on proposed theories of cytokine-induced dysregulation of HPA axis activity and its relation to fatigue.

Chronic Stress, Fatigue, and Cytokines: Relevance for Disease Processes

There is a possibility that the chronic prevalence of fatigue in otherwise healthy individuals may also increase their risk for cardiovascular disorders via a cytokine-mediated response. We already mentioned that vital exhaustion is characterized by a generalized increased inflammatory profile. Not surprisingly, individuals who experience vital exhaustion also report a general lack of energy and some symptoms of depression, such as hopelessness. A relatively recent large-scale study indicated that vital exhaustion was independently associated with a twofold risk of mortality from coronary heart disease in older men. In addition, a recent study reports that vital exhaustion is a significant independent risk indicator for first stroke in middle-age men and women, implying that this state of persistent and excessive fatigue (and its negative effects) is not necessarily a consequence of existing cardiovascular disorders. Given that elevations in IL-6 as well CRP are associated with greater risk of peripheral vascular disease, myocardial infarction, and stroke and that elevations in these inflammatory markers are found in patients with vital exhaustion, it is not unreasonable to suspect that chronic elevations in inflammation associated with vital exhaustion lead over time to an increased risk

for deleterious cardiovascular events. Longitudinal studies with younger, chronically stressed men and women will help to elucidate the potential effects of persistent stress and fatigue on glucocorticoid resistance, cytokine balance, and subsequent immune response over time.

Obviously, alterations in cytokines that are associated with chronic stress and fatigue affect more than cardiovascular disease progression. Increases in pro-inflammatory cytokines associated with chronic stress and fatigue may directly exacerbate disease progression for disorders such as rheumatoid arthritis, MS, and diabetes, which are already characterized by increased pro-inflammatory activity. What remains uncertain is whether persistent fatigue in clinical populations may affect tolerance for other therapies. For example, it will be important to better understand whether patients with higher fatigue (and higher inflammation) respond more poorly to inflammation-inducing treatments such as INF treatment, chemotherapy, and radiation, both in terms of poorer physiological tolerance or response to treatment and in terms of the psychological ramifications of treatment, such as increased depression. To date, there are very few studies that have examined such potential differential psychological and physiological responses with respect to fatigue. These studies will be very important because they may identify a potential need to ameliorate fatigue in some patients either before or during treatment to enhance psychological and physiological responses to treatment.

Conclusion

Cytokines have emerged as not only important mediators of immune function but also as immunotransmitters that have widely varying and far-reaching effects on other physiological systems, including the CNS and HPA. Imbalances in cytokines and their effects on psychosocial and physiological functioning are reflected in numerous populations of relevance to chronic stress and fatigue, including (but not limited to) cancer, cardiovascular disorders, MS, and CFS.

In addition, because of their far-reaching effects, it is becoming clearer that cytokines play an important role in the psychophysiological states of chronic stress and fatigue. It is our hope that continued rigorous research in these areas will further elucidate the linkages between cytokines and these psychological states, as well as identifying effective behavioral and/or pharmacological interventions aimed at relieving the associated symptomatology.

Glossary

Corticotropin-releasing hormone (CRH)

Brain peptide that mediates the neural control of adrenocorticotrophic hormone (ACTH) release from the anterior pituitary gland. CRH has also been implicated as a central neurotransmitter involved in anxiety and depression.

Cytokines

These are biologically active peptides that elicit responses from the endocrine, immune, and neurotransmitter systems by acting on specific cytokine receptors situated on the cell membrane. Cytokines have a wide range of actions that include cellular differentiation, growth, stimulation of antibody synthesis, and inflammatory changes. Regarding the psychopathology of depression, **pro-inflammatory cytokines** (e.g., interleukin (IL)-1, IL-6, tumor necrosis factor (TNF)- α , and interferon (IFN)) have been shown to increase in the blood and brain where they contribute to the symptoms of depression (such as anhedonia [loss of feeling of pleasure], anorexia, sleep disturbance, and anxiety). Pro-inflammatory cytokines are also thought to increase neuronal apoptosis that could contribute to neurodegeneration. The rise in the pro-inflammatory cytokines

in depression is associated with a reduction in the **anti-inflammatory cytokines** (such as IL-4 and IL-10) that normally counteract the effects of the pro-inflammatory cytokines.

Term used by a founder of psychoendocrinology, Hans Seyle, to describe the long-term effects of stressful stimuli that result in hypertrophy of the endocrine and immune organs. Seyle showed that if the stress persists, this eventually leads to complete exhaustion of the animal and death.

Tendency towards the establishment of a stable internal environment. This is usually achieved by biological mechanisms that are activated by a negative feedback mechanism. Thus the rise in the concentration of a hormone, immune regulator, or neurotransmitter triggers an inhibitory mechanism that slows the further release of active molecule.

Presence of an excess of adrenocortical hormones (usually cortisol in humans or corticosterone in nonprimates) frequently found in major depression.

Term used to describe the different types of molecules that accumulate in tissues as part of the inflammatory process. In depression, the rise in pro-inflammatory cytokines triggers a cascade of changes that result in the rise in prostaglandin E2 and nitric oxide. Together with the glucocorticoids and pro-inflammatory cytokines, these inflammatory mediators are thought to contribute to the increase in neuronal apoptosis and possible neurodegenerative changes associated with chronic depression.

This is the mechanism whereby the increase in, for example, circulating glucocorticoid hormones activates the central glucocorticoid receptors that then inhibit the further release of corticotropin-releasing hormone. This reduces the release of adrenocorticotrophic hormone from the anterior pituitary gland thereby reducing the further synthesis and release of glucocorticoids from the adrenal gland.

Term used to describe the proliferation of new neurons in the brain. Experimental evidence shows that stress inhibits the development of new pyramidal cells in the hippocampus due to the reduction in availability of neurotrophic factors such as brain-derived neurotrophic factor

General adaptation syndrome

Homeostasis

Hyper-cortisolemia

Inflammatory mediators

Negative feedback mechanism

Neurogenesis

(BDNF). Chronic antidepressant treatment has been shown to reverse the effect of stress on the neurogenesis of cells in the hippocampus.

Introduction

The causal relationship between negative emotions and psychological distress on physical health has been confirmed in recent years by epidemiological studies in which an increase in the prevalence of coronary heart disease, osteoporosis, diabetes, and dementia have been associated with chronic stressful life events. Research has largely focused on changes in neurotransmitter function, as well as the endocrine and immune systems, in explaining the basis of the causal relationship between stress and ill-health as these systems provide the main pathways of communication between the brain and the peripheral organs. The anatomical links between the brain, endocrine system, and peripheral nervous system is illustrated in Figure 1.

Psychological Stress and Activation of the Endocrine System

It is well established that, in the face of any threat, either real or perceived, an organism mounts a series of co-ordinated and specific hormonal, autonomic, immune, and behavioral responses that allow it to fight, or escape from, the threat. Normally, the characteristics and intensity of the response to the stress matches that posed by the threat and the duration of

the response is normally no longer than is necessary to achieve a successful outcome. If the response to the stress is inadequate or excessive then it could give rise to pathological changes.

The scientific basis of adaptation to stress was suggested by Walter Cannon who, in the early part of the twentieth century, introduced the concept of homeostasis. This involved the initiation of the fight or flight response whereby changes in the sympatho-adrenomedullary system co-ordinated the physiological aspects underlying homeostasis. This concept was developed further by Hans Seyle (1936) who stressed the importance of the hypothalamic-pituitary-adrenocortical (HPA) axis in the stress response. Seyle described the general alarm reaction as an early response to a noxious stimulus that was characterized by a nonspecific activation of the endocrine and the sympatho-medullary system. Continued exposure to the same stressful stimulus was proposed to lead to long-term changes in the endocrine and immune systems. These were characterized by hypertrophy of the pituitary and adrenal glands. Seyle termed this chronic effect of stress the general adaptation syndrome. An organism could recover from the changes once the stressful stimulus was terminated by exhaustion, but death could occur if the stress continued.

The concept of stress being physically and functionally damaging was initially thought to be due to the hypersecretion of glucocorticoids, a concept that was supported by the observation that various diseases of the adrenals and pituitary were associated with psychopathological changes that resolved when the HPA axis was normalized. However, it is now

Figure 1 The relationship between stress and neuroendocrine system. (+), positive feedback; (-), negative feedback; ACh, acetylcholine; ACTH, adrenocorticotrophic hormone; AVP, arginine vasopressin; NE, norepinephrine; PVN, paraventricular nucleus.

accepted that the stress response is often beneficial in protecting the organism from harmful situations and that adaptation, a learned response, is important in adjusting to future adverse situations. Nevertheless, problems arise when stress becomes repetitive and sustained, and adaptation becomes difficult. This forms the basis of stress-induced ill-health that can result in hypertension, hypercortisolism, abnormal immune function, and ultimately mental ill-health, particularly depression.

Stress and the Role of Corticotropin-Releasing Hormone Receptors

Depression may be interpreted as the result of the sustained hyperactivity of the stress axis that results from the overactivity of the corticotropin-releasing hormone (CRH) pathway, an effect that is correlated with the hyperactivity of the central and peripheral sympatho-adrenal system and the secretion of the glucocorticoids. In addition to the psychological effects of maladaptation to stress, physical damage may also occur as indicated by a loss of bone mass, hippocampal atrophy, and neurodegeneration.

CRH produces its effects by activating CRH-1 and CRH-2 receptors. It is now evident that the fight or flight response involves activation of CRH-1 receptors whereas the much slower response system that promotes recovery and adaption to stress, is activated by urocortin acting on CRH-2 receptors.

The fight or flight response, the fast response, occurs when CRH activates CRH-1 receptors on the paraventricular nucleus (PVN) of the hypothalamus, together with noradrenergic neurons of the locus coeruleus. CRH-1 receptors also occur on the corticotrophs in the anterior pituitary which, on activation, results in the release of the adrenocorticotrophic hormone (ACTH). This is followed by the activation of the adrenal cortex by ACTH that leads to the synthesis and release of glucocorticoids.

Epinephrine and norepinephrine are released from the adrenal medulla in response to the stress-induced increase in the activity of the locus coeruleus. The fast response is particularly sensitive to the negative feedback activation of the mineralocorticoid receptors, under conditions of normal stress, or glucocorticoid receptors, under conditions of high stress.

It is now apparent that the slow stress response system is driven by the peptides urocortins 2 and 3, two peptides that are distinct from the CRH family of peptides. The urocortins have been identified as selective, high-affinity ligands for CRH-2 receptors. They are synthesized in the hypothalamus and amygdala and their terminals are located in the hypothalamus and brain stem where the CRH-2 receptors

are mainly located. The CRH-2 receptors are thought to facilitate coping and behavioral adaptation. Further, the central administration of these peptides evokes anxiolytic-like responses whereas CRH causes anxiogenic effects in rodents.

The stress response to adverse stimuli is driven not only by CRH but also by arginine vasopressin (AVP), a peptide that is synthesized in a different region of the PVN of the hypothalamus to CRH. Stress increases the proportion of cells that synthesizes AVP. The secretion of CRH is usually accompanied by AVP but whereas AVP usually has a low efficacy for stimulating the release of ACTH compared to CRH, AVP potentiates the effects of CRH thereby enhancing ACTH release. Chronic stress desensitizes the CRH-1 receptors in the pituitary gland but, under these circumstances, the AVP receptors are sensitized thereby sustaining the release of ACTH and the activation of the adrenal cortex.

In addition to its role in stimulating the HPA axis and the central sympathetic system, CRH neurons are activated by different neurotransmitters from several brain regions. Excitatory inputs to the CRH pathways include serotonin, norepinephrine and peptides such as neuropeptide-Y, while the inhibitory inputs include γ -aminobutyric acid (GABA) and the opioids.

Different types of stressful stimuli activate the CRH pathway in different ways. Thus painful stimuli (infections, inflammation, toxic agents, hypoglycemia, and hypo- and hypertension) activate monosynaptic pathways to the CRH neurons. By contrast, stressful, psychological stimuli activate neurons of the limbic-cortical region that subserve nociception, emotional, and cognitive functions. It now appears that these emotional circuits in the central amygdala, frontal cortex, and hippocampus project to a GABAergic network that surrounds the PVN. The effect of this GABAergic system on the function of the hypothalamus varies and can be either disinhibitory to CRH release, when the input is from the amygdala, or inhibitory when the input is from the hippocampus. This pathway functions to process cognitive and emotional aspects of a stressful situation to be assessed.

Depression and the Hypothalamic-Pituitary-Adrenocortical Axis

Some 50 years ago, Board and colleagues (1956) first reported that cortisol was elevated in the plasma of depressed patients but it was Sachar and coworkers (1970) who showed that the hypersecretion of cortisol was accompanied by an altered circadian pattern. They also showed that the frequency, magnitude, and duration of the secretory bursts of cortisol

Table 1 Changes reported to occur in the hypothalamic-pituitary-adrenal axis of patients with major depression

<i>Short-term stress: acute exposure</i>	<i>Pathophysiological effects: chronic stress</i>
Energy mobilization	Myopathy, fatigue, steroid-induced diabetes
Control of stress reactions	Hypertension
Increased vascular tone	Osteoporosis
Suppression of growth	Amenorrhea, infertility
Suppression of fertility	Impaired immune function
Anti-inflammatory effects	Affective disorders
	Neurotoxicity

secretion were elevated. More recently, it has been shown that a high morning salivary cortisol concentration is a possible risk factor for depression. The possible link between the hypersecretion of cortisol and the symptoms of depression is also supported by the observation that, therapeutically, glucocorticoids can precipitate depression even in those who were not apparently vulnerable to the condition. Conversely, low doses of glucocorticoids are administered to rodents have rewarding effects, changes that have been attributed to the stimulation of the mesencephalic dopaminergic system. It is possible that this system forms part of the coping strategy to stress whereas chronic, high glucocorticoid concentrations are causally responsible for provoking both anxiety and depression. [Table 1](#) summarizes the major changes that have been reported in the HPA axis of patients with major depression.

The Chronic Effects of Stress: Depression and Neurotoxicity

Several studies have reported that there is a reduction in the volumes and metabolic activity of the hippocampus, amygdala, and pre-frontal cortex in depressed patients. Such changes could be associated with the cause of depression, or could be a consequence of depression. Whatever the relationship, it is apparent that the shrinkage of the hippocampus could account for the inability of the patient to readily adapt to stressful situations. Whether the decrease in the hippocampal volume is attributable to hypercortisolemia, as is frequently stated, is not certain as patients with posttraumatic stress disorder also have a reduced hippocampal volume but frequently suffer from hypocortisolemia.

The connection between the shrinkage of some of the limbic regions and neuronal atrophy has also been the subject of debate. For example, some investigators have reported no signs of increasing neuronal death in the hippocampus of depressed patients, and

while there is evidence that the gray matter and glia numbers are reduced in the prefrontal cortex of depressed patients, there does not appear to be an equivalent loss of neurons. By contrast, animal studies clearly indicate that chronic stress has a profound effect on the structure of hippocampal neurons, changes that are effected through the actions of the glucocorticoids. For example, the dendrites of the pyramidal cells in the CA3 region of the hippocampus retract after an acute stress and become irreversibly damaged if the stress becomes chronic. Other experimental studies have shown that the CA1 neurons of the hippocampus are particularly vulnerable to neurotoxic damage caused by glucocorticoids. Glucocorticoids are known to block glucose uptake by the neurons thereby initiating the excitotoxic cascade of changes caused by the excessive activation of *N*-methyl-D-aspartate (NMDA) receptors. Furthermore, glucocorticoids block the reuptake of glutamate into glia and thereby enhance the concentration of the excitatory amino acid in the vicinity of the neurons. In addition for these changes that could account for glucocorticoid induced neurotoxicity, there is also evidence that stress, and glucocorticoids, suppress neurogenesis. Neurogenesis is enhanced by neurotrophic factors such as brain-derived neurotrophic factor (BDNF) and by the activation of 5-HT_{1A} receptors.

In rodent studies, stress has been shown to increase the turnover of serotonin in the prefrontal cortex, nucleus accumbens, amygdala, and lateral hypothalamus. These effects of stress are mediated through the glucocorticoids, which have major effects on the expression of both the 5-HT_{1A} and 5-HT_{2A} receptors. It is known that the 5-HT_{1A} receptors are under the tonic inhibition by the adrenal steroids, by activation of the type 1 glucocorticoid receptors. Conversely, 5-HT_{2A} receptor expression is increased following chronic stress, or by exogenous glucocorticoid administration, and decreased in response to adrenalectomy. Thus the 5-HT_{1A} and 5-HT_{2A} receptors appear to play an antagonistic role in stress which may help to explain why elevated basal cortisol concentrations are attenuated in depressed patients by the 5-HT_{1A} agonist ipsapirone. These results suggest that the dysfunctional HPA axis in depression results in a glucocorticoid subsensitivity of the postsynaptic 5-HT_{1A} receptors. The link between the serotonergic system, stress, and the effect of stress has been the subject of a recent review.

The results of these experimental studies support the hypothesis that stress and glucocorticoids reduce neurotrophic factor synthesis in the hippocampus, a process that contributes to hippocampal damage. There is evidence that the cellular actions of BDNF

and serotonin are interlinked and a reduction in BDNF reduces the density of 5-HT_{1A} receptors and increases that of 5-HT_{2A} receptors in the frontal cortex. This results in increased aggressiveness in BDNF-deficient rodents, a similar situation to that occurring following the drug-induced depletion of serotonin. These changes probably contribute to the reduction in neurogenesis thereby resulting in a reduction in the size of the hippocampus that is reported to occur in patients with chronic depression. Conversely, chronic antidepressant treatment has been shown to increase neurogenesis; this correlates with the attenuation of the symptoms of depression.

It is still uncertain from the results of these studies whether the shrinking of the hippocampus in patients with chronic depression is the cause or the result of stress. If a smaller than normal hippocampus is genetically determined, as seems possible from the results of primate studies, then it seems possible that this could contribute to an increased vulnerability to the effects of stress. For example, this could result in a decreased ability of the patient to cope with stress. It is also possible that while there may not be gross changes in the cytoskeleton, there could be changes in the synaptic plasticity that would not be evident in the imaging studies on patients with depression. Thus, while it is presently uncertain that chronic stress results in increased neuronal apoptosis, partly because of the limited sensitivity of the imaging methods available, experimental studies clearly indicate that persistent high concentrations of glucocorticoids cause atrophy of the hippocampus, prefrontal cortex, amygdala, and other brain regions that are considered to be anatomically associated with depression. The changes in the monoamine neurotransmitters in the brain, which form the basis of the amine hypothesis of depression, are therefore postulated to occur as a consequence of the primary changes in the HPA axis and immune system.

If the vulnerability of the adverse effects of stress is a causative factor in the etiology of depression, it would be anticipated that drugs activating the central glucocorticoid receptors would have antidepressant activity. There is some clinical evidence to support this view. Thus DeBattista and colleagues have reported that the intravenous administration of a high dose of cortisol (15 mg) produces an improvement in the symptoms of depression while in recent controlled studies the glucocorticoid antagonist mifepristone has been shown to have a significant antidepressant effect in patients with psychotic depression. This suggests that the glucocorticoid antagonists block the action of endogenous cortisol on glucocorticoid receptors in afferent pathways. Presumably a very high bolus dose of cortisol acts by desensitizing

these receptors. From the results of the experimental and clinical studies, it may be concluded that the overactivity of the CRH system plays a crucial role in the psychophysiology of depression. This could result in long-term structural and functional changes in neurons in the limbic system that may contribute to increased apoptosis. This raises the important question whether the neurodegenerative changes that occur in depression could contribute to the onset of dementia in vulnerable individuals. Hypercortisolemia is a common feature of chronic depression and some types of dementia while qualitatively similar changes have been reported to occur in patients with depression, and also in those suffering from dementia.

Changes in Pro-Inflammatory Cytokines in Depression

The evidence implicating a role for the pro-inflammatory cytokines in the etiology of depression is provided by studies on the changes in the concentrations of interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)- α in the plasma of depressed patients. Additional evidence is provided by the effects of interferon (IFN)- α on nondepressed patients being treated for hepatitis or malignancy. The results of such studies imply that the pro-inflammatory cytokines are causative factors in the symptoms of major depression. These symptoms include depressed mood, anxiety, cognitive impairment, lack of motivation, loss of libido, sleep disturbance, and deficits in short-term memory. These symptoms usually disappear once the plasma cytokine concentrations normalize. The changes appear to be a consequence of the neurotransmitter and endocrine changes induced by the cytokines rather than the pathological condition for which the treatment has been given. It is perhaps not surprising therefore to find that the symptoms of depression frequently occur in patients who are recovering from a chronic infection, those with multiple sclerosis, allergies, and rheumatoid arthritis. In all these situations, pro-inflammatory cytokines are known to be overexpressed. The initial studies linked depression with an abnormality of the immune system, such as impaired mitogen-stimulated lymphocyte proliferation and reduced natural killer cell activity in untreated depressed patients. These immune changes largely returned to normal once the patient has recovered from the depressive episode.

Some research into the immune changes that occur in depression has concentrated on pro- and anti-inflammatory cytokines, soluble cytokine receptors, and acute-phase proteins. For example, positive acute-phase proteins have been shown to increase,

while the negative acute-phase proteins decrease, in depression. These changes are known to be a consequence of the stimulant action of IL-6 on the liver. In addition, Song et al. (1994) showed that complement proteins (C3, C4) and immunoglobulin M are increased in depressed patients. Such changes are evidence that immune activation involves both the inflammatory cytokines and the B cells that are activated by the pro-inflammatory cytokines. Further evidence of immune activation in depressed patients is provided by the studies showing that the plasma concentrations of IL-1, IL-6, IFN, soluble IL-6, and soluble IL-2 receptors, and the soluble IL-1 receptor antagonist, are raised. These changes are correlated with a rise in acute-phase proteins. Effective antidepressant treatments attenuate these immune changes. In addition to the changes in the pro-inflammatory cytokines, there is also evidence of an increased number of T helper, T memory, activated T cells, and B cells that act as a source of plasma cytokines. From these changes, it would appear that in depression there is an imbalance between the inflammatory and anti-inflammatory arms of the immune system, the cytokines from the inflammatory Th-1 pathway (such as IFN- γ) becoming predominant over those of the anti-inflammatory Th-2 pathway (such as IL-10). A recent study has shown that the Th-3 cytokine, transforming growth factor (TGF)- β 1, whose function is to re-establish the balance between the Th1 and Th2 pathways, is increased in depressed patients following effective antidepressant treatment. Although TGF is reported to be a regulatory cytokine that maintains the balance between the pro- and anti-inflammatory cytokines, precisely how the changes are established is presently unclear. It is of interest that many clinical and experimental studies show that the chronic administration of antidepressants normalize the immune changes thereby suggesting that antidepressants have an anti-inflammatory action. This suggests that antidepressants may modulate monoaminergic function indirectly as a consequence of their actions on the disturbed immune system and the HPA axis.

Conclusion

Chronic stress, by initiating changes in the HPA axis and the immune system, acts as a trigger for depression. There is experimental and clinical evidence that the rise in the concentrations of pro-inflammatory cytokines and cortisol, which occurs following chronic stress and in depression, contribute to the neurodegenerative changes in the hippocampus, prefrontal cortex, and amygdala. The structural changes in the brain could contribute to the chronicity of

depression and be a prelude to dementia. Effective antidepressant treatment attenuates the endocrine and immune changes thereby suggesting that antidepressants have central anti-inflammatory actions that may contribute to their therapeutic efficacy.

Effects of Stress on Cytolytic Lymphocytes

Stress, Cytotoxic Lymphocytes, and Human Diseases

Glossary

<i>Cytokines</i> (<i>lymphokines</i>)	Peptides or glycopeptides that act in a manner analogous to hormones to regulate the immune system.
<i>Cytolytic</i> (<i>cytotoxic</i>) <i>lymphocytes</i>	White blood cells that have the capacity, by means of direct cell-to-cell contact, to cause the lysis and subsequent death of target cells.
<i>Large granular lymphocytes</i> (<i>LGLs</i>)	Lymphocytes that are larger and contain more intracellular granules than most lymphocytes. These lymphocytes, called natural killer (NK) cells, can form conjugates with and lyse target cells, such as tumor cells or virally infected cells, without the mediation of antigen recognition. Association of an antibody against the target cell with such LGLs through Fc receptor interaction with the Fc portion of the antibody can result in a type of cytotoxicity called

antibody-dependent cellular cytotoxicity (ADCC). Exposure of the LGL to activating cytokines, such as interleukin-2, results in a more potent cytotoxic cell called the lymphokine-activated killer cell (LAK).

T lymphocytes

White blood cells that have on their surface membranes an antigen recognition structure, the T cell receptor. Most cytolytic T lymphocytes are CD8 T cells that can interact with the major histocompatibility complex (MHC) peptides on the surface of target cells.

Types of Cytotoxic Effector Cells

Lymphocyte-mediated cytotoxicity is a form of cellular immunity whose existence was first documented in experiments on transplant rejection. In 1960, Andre Govaerts showed that lymphocytes from dogs that had received and rejected a kidney transplant destroyed cultured kidney cells from the donor dog *in vitro*. Govaerts' experiments provided the first proof for the existence of cellular immunity. In 1967, K. Theodor Brunner, Albert A. Nordin, and Jean-Charles Cerottini developed the radioactive chromium (^{51}Cr)-release assay as a quantitative tool to assess lymphocyte-associated cytolysis. Radioactive chromium binds to intracellular proteins and is used to label target cells. Release of intracellular proteins occurs relatively quickly upon lysis of target cells, and the amount of released ^{51}Cr is proportional to the amount of lysed cells. Use of this assay provided proof for the existence of cytotoxic T lymphocytes (CTLs) that, without antibodies or complement, specifically kill the target cells toward which they had been sensitized through immunization or transplantation.

Moreover, the cytolytic activity measured with this assay reflected changes in the frequency, rather than in the lytic capacity, of individual effector CTLs.

The ^{51}Cr -release assay also allowed the discovery of other types of lymphocyte-mediated cytolytic activities. The second model of cytolysis, defined by Peter Perlmann and Goran Holm in 1968, required that the target cell first react with antibodies to activate the cytolytic mechanism. This antibody-dependent cellular cytotoxicity (ADCC) was nonspecific, was present in nonimmunized individuals, and lacked memory, i.e., the cytolytic activity did not increase with immunization. Cells that mediate ADCC were termed killer (K) cells and were shown to inhibit tumor growth upon activation with cytokines or biological response modifiers (lymphokine-activated killer [LAK] cells).

A third type of lymphocyte-mediated cytolysis was discovered by several immunologists, including Ronald B. Herberman, Rolf Kiessling, and George Klein. They were looking for tumor-specific cellular immunity, but found that lymphocytes from both cancer patients and normal controls could lyse tumor cells. These lymphocytes were called natural killer (NK) cells since their activity against tumor-transformed and virus-infected cells occurred naturally without immunization. Most NK cells are large granular lymphocytes (LGLs) and are constitutively cytotoxic.

Cytolytic mechanisms involving nonlymphocytic cells, such as monocytes through their expression of tumor necrosis factor (TNF)- α or nitric oxide, are not discussed in this article but can be assessed using the same approaches.

Mechanisms of Target Cell Killing

Lymphocyte-mediated cytolysis can be conceptually divided into three distinct stages: conjugate formation (binding of effector to target), triggering (signal transduction), and lethal hit (granule exocytosis). Studies of lytic (killers), nonlytic conjugate-forming (binders), and non-conjugate-forming (free) cells suggest that the ability to perform the different stages of cytotoxicity may be acquired at different points in cell maturation, with lytic function preceding responsiveness to target cell-specific triggering. Once triggered, the cytolytic process may propagate as effector cells detach from lysed targets and recycle to initiate new lytic interactions.

Direct membrane-to-membrane contact between cytolytic and target cells (conjugate formation) is a prerequisite for lysis to occur. Cell membrane receptors and adhesion molecules mediate conjugation,

and transmission electron microscopy reveals extensive cellular membrane interdigitation at the contact region, forming an immunological synapse. In the case of CTLs, target cell adhesion results from T cell receptor–major histocompatibility complex (MHC)–peptide interactions and adhesion strengthening steps, although several other molecules mediate binding of the different types of lymphocytolytic effectors to target cells. In the case of NK cells, effector function involves receptors and ligands on the surface of the effector cells and their targets, but does not result from antigen recognition. Following the effector cell–target cell direct contact, the intracellular cytotoxic granules move to the immunological synapse. Perforin from these intracellular vesicles facilitates the release of the granzymes and the passage of these serine protease through target cell membranes by a process involving endocytosis, and perhaps pore formation. The most abundant granzymes are granzyme A and B. They induce cell death through alternate and nonoverlapping pathways. Granzymes initiate cell death mechanisms that operate through the activation of apoptotic cysteine proteases (caspases), but can also cause cell death in the absence of activated caspases. The second pathway involves the engagement of the so-called death receptors such as Fas/CD95 on target cells by their ligands (FasLs) on cytolytic cells, resulting in classical caspase-dependent DNA fragmentation and apoptosis. Granule exocytosis also requires extracellular calcium for the regulated secretion of lytic granule components, binding of the secreted perforin to the membrane of the target cell, and the polymerization of perforin to polyperforin. The antigen-specific degranulation that occurs in CTLs leads to the nascent appearance on the lymphocyte surface of a granule-associated protein, CD107. Detection of this marker using flow cytometry forms the basis of a new type of assay for functional assessment of CTLs.

Although perforin lyses a variety of target cells nonspecifically, cytolytic cells are generally more resistant to the lytic effect of perforin. The protective mechanism is insufficiently characterized at present. However, in some cases a phenomenon known as fratricide can be elicited by T cells presenting antigens to other CTLs, resulting in perforin-mediated cytolysis. These results may be important in the regulation of CD8 $^{+}$ CTLs in immune responses.

Effects of Stress Hormones on Cytotoxic Lymphocytes

Elevations in cortisol, norepinephrine (NE), and epinephrine (E) may be accompanied by decrements in

immune function. Adrenal cortical hormones may directly impair or modify several components of cellular immunity, including the cytolytic activity of T lymphocytes and NK cells. Corticosteroids inhibit cellular responses to antigens and impair NK cell activity. Corticosteroids may communicate with lymphocytes via transcriptional cytoplasmic receptors. Hence, the literature supports the concept that elevated levels of cortisol are associated with impaired immune system functioning with accompanying depression of cytokine production. Sympathetic noradrenergic fibers innervate both the vasculature and parenchymal regions of several lymphoid organs. Elevations in peripheral catecholamines may depress immune functioning. This interaction is likely mediated by β -adrenergic receptors on lymphocytes. Neuropeptide Y (NPY) also is stored in sympathetic nerve terminals and is released along with catecholamines during stress-induced activation. It is known to depress NK cell cytotoxicity *in vitro*. In contrast, pituitary and adrenal peptide stress hormones such as met-enkephalin, β -endorphin, and substance P stimulate T cell and NK cell responses. Lymphocytes have receptors for NPY and for many other neurotransmitter/neurohormones, including serotonin, cholinergic agonists, and β -adrenergic agonists.

Effects of Stress on Cytolytic Lymphocytes

Biological, psychological, and social factors that are involved in physiological stress responses and capable of immunomodulatory effects are discussed in the following sections.

Biophysical Stimuli

Several biophysical stimuli, including tobacco, ethanol, and recreational drug usage, are associated with immunomodulation. Smoking tobacco is reported to be associated with significant decreases in cytotoxic T cells. Ethanol use is correlated with depressed cell-mediated immunity and diminished NK cytotoxicity. Intravenous drug usage is associated with depressed cellular immune functioning. The specific mechanisms by which these substances affect immune functioning have not been fully elucidated, but some of these substances are associated with alterations in those physiological stress response systems noted previously. For instance, nicotine in cigarette smoke is associated with catecholamine discharge, and ethanol consumption is also linked with catecholamine elevations due to blockage of reuptake.

Psychological Factors

Acute psychological stress influences cellular immune functions. Data support the hypothesis that altered trafficking of lymphocytes with cytolytic potential occurs as a component of the fight-or-flight response to an acute stressor. Depending on the time frame of measurements, early increases in circulating CD8 T cells and NK cells can be seen, along with an increase in the ability of NK cells to kill target cells. Later, however, the per cell lytic activity decreases. For example, in a field study of first-time tandem parachutists, immediately after jumping from an airplane, elevation in noradrenalin levels was observed that correlated with elevated levels of peripheral blood CD8 T cells and NK cells and with an increase in functional capacity of NK cells. Within 1 h, however, the cytotoxic cell numbers and function decreased significantly below starting values. Similar results are observed in laboratory studies using techniques such as mental arithmetic, speech stressors, or discussions of marital discord. Such data support the hypothesis that altered trafficking of lymphocytes with cytolytic potential occurs as a component of the fight-or-flight response to an acute stressor. The resultant *in vivo* exposure of immune cells to neuropeptides, hormones, and cytokines leads to altered functional responses in CD8 T cells and NK cells.

Clinical depression or depressed affect is linked with impaired cellular immune functioning, although the literature regarding this relationship is controversial. Depression is associated with neuroendocrine abnormalities, including hypercortisolemia and elevated NPY. The impact of depression on immunity may be stronger in older subjects and in those with more severe depression. Severity of depressive symptomatology was associated with decreased NK activity. Depressive symptoms were predictive of decrements in NK activity among women when measured before and after the death of their husbands. Sleep deprivation, a condition often associated with depression, leads to reduced NK cytotoxicity.

Intrusive thoughts to an adverse situation or event are related to changes in immunological parameters. In the months following Hurricane Andrew, there was a lower level of NK cytotoxicity in those individuals of a community sample who had intrusive cognitions regarding the storm. There are several reports of reduction in immune function in patients with major depressive disorders and in persons undergoing severe life stress. There is an association between increased sympathetic nervous system activity and reduced NK cell activity in depression and Alzheimer caregiver stress. Plasma concentrations of NPY in

depressed patients were elevated compared to controls. In both depressed patients and in Alzheimer spousal caregivers, circulating concentrations of NPY, but not catecholamines, were inversely correlated with NK activity.

Social Variables

Social stressors are associated with elevations in stress hormone levels and impaired immune functioning in animals and humans. Social stressors most commonly associated with immunomodulation of cytotoxic activity in studies of humans include loneliness, marital disruption, job loss, family illness, and bereavement. Urinary excretions of NE and E are elevated in bereaved subjects and in subjects threatened with a loss as compared to normals. Animals subjected to uncontrollable stressors had immune system decrements such as decreased NK cell cytotoxicity. The experience of sustained stressful periods (e.g., studying for medical school examinations) by normal individuals is associated with poorer control of latent viral infections, impaired lymphocyte production of cytokine, diminished T cell killing of virally infected cells, and decreases in NK cell number and lytic activity. It is suggested that perception and utilization of social support buffers the effects of self-preoccupying helplessness in the face of elevated life stress and that this provides the opportunity for task-oriented thinking and active coping. Thus, disengagement from active, adaptive coping, possibly accompanying each of the previously noted stressors, may lead to self-preoccupying helplessness and consequent physiological arousal. Such a sequence of events could explain the catecholamine and glucocorticoid elevations and impaired cellular immune functioning repeatedly associated with these conditions. In a series of behavioral immunology studies in which social support, mood, and NK activity were evaluated among breast cancer patients, a lack of social support predicted poorer NK activity. A longitudinal study of homosexual men noted that NK cytotoxicity was decreased in men who had lost friends and/or partners to AIDS.

Stress, Cytotoxic Lymphocytes, and Human Diseases

Cytolytic cells are critical for immune surveillance against fungal, bacterial, and viral infections. They also play a vital role in cellular resistance to malignancy and tumor metastasis. Granule-mediated cytotoxicity is the major mechanism by which lymphocytes kill viruses, intracellular bacteria, and tumors. Acute psychological stress is often followed by increased susceptibility to infections.

A strong correlation exists between levels of psychological stress and the development of colds in rhinovirus-innucleated volunteers as well as between stress and upper respiratory infections, necrotizing ulcerative gingivitis infections, and acute Epstein-Barr virus (EBV) infection (mononucleosis). Because the cellular immune system has a major role in the prevention of viral infections and in the suppression of the activation of latent viral infections, any factor that changes the function of the immune system may alter disease progression. Abnormalities of the stress response have been hypothesized as a potential trigger or mediator of chronic fatigue syndrome (CFS). In CFS, the activity of NK cells is reduced relative to controls. In CFS patients, intracellular levels of perforin are reduced relative to controls, in both NK cells and in CD8 T cells. Stress may be a precipitating factor, which promotes neuroendocrine and immune dysfunction in vulnerable individuals, resulting in an increased risk of developing chronic multisymptom illness, such as CFS as well as mood/anxiety disorders.

Antibody titers to EBV are consistently elevated in stressed subjects. Reactivation of latent herpesvirus infections, including EBV, cytomegalovirus, human herpes viruses type 6 (HHV-6), and herpes simplex types 1 and 2 (HSV-1 and -2), is an important consequence of the loss of cellular immune function. Elevated antibody titers to EBV have been found to be associated with an avoidant style of cognitive processing in college students (suggesting indirectly a decrement in cellular immune function and poorer control of latent herpesviruses).

In HIV infection, the antiviral role of CD8 T cells and NK cells is thought to be of great importance. Mathematical modeling suggests that, on average, an HIV-specific CD8 T cell can kill 0.7 to 3 target cells per day. Some HIV-infected individuals, called long-term survivors, survive for longer periods than others; a subset of these remain asymptomatic for extended periods and are denoted long-term nonprogressors. Among a myriad of factors that may contribute to disease progression in HIV/AIDS, the stress/endocrine/immune connection should not be neglected. In a pilot study of long-term nonprogressors, it was noted that men who had very low CD4 counts had normal NK cytotoxicity. This suggests that natural NK cell immunity may act as a compensatory protective mechanism in the face of virtual absence of T helper cells.

Empirical and Clinical Studies of Death Anxiety
Theories of Death Anxiety

Glossary

<i>Existentialism</i>	A philosophical position that emphasizes the individual as alone in the world and responsible for his or her own life and values.
<i>Hospice</i>	A programmatic approach to providing comfort to terminally ill people and their families.
<i>Ontological confrontation</i>	An experience that forces one to acknowledge the reality and salience of death.
<i>Near-death experience (NDE)</i>	An altered state of consciousness usually occurring after traumatic injury that is often recalled as a comforting and revelatory episode.
<i>Palliative care</i>	Medical and nursing procedures designed to relieve pain and suffering rather than extend life by all possible means.
<i>Thanatophobia</i>	Fear of death and of whatever has become associated with death.

Empirical and Clinical Studies of Death Anxiety

The experience of anxiety is much the same whatever its source: a sense of danger and foreboding accompanied by physical manifestations such as changes in heart rate and respiration. Precisely how death

anxiety differs from other forms of anxiety – if at all – is a question that has received little attention. Instead, most academic studies have relied on self-report questionnaires. Respondents usually respond by agreeing or disagreeing with direct questions such as “I fear dying a painful death.” Fortunately, there have also been multilevel and interview studies that enhance our understanding.

Self-Reported Death Anxiety in Everyday Life

Most studies have been conducted with healthy adults, with attention given to their level of anxiety and gender, age, and other demographic variables.

The general population: How anxious about death? Most adults in the United States report themselves as having moderately low levels of death anxiety. This consistent finding often has been interpreted to mean that we labor to keep our anxieties hidden both from ourselves and others. Supporting this interpretation are studies that have detected physiological indications of stress at the same time that subjects report feeling no death-related anxiety at all. It is therefore argued that we are all anxious about death on the gut level, though are reluctant to admit so. An alternative interpretation is that we usually have a low walking-around level of death anxiety that only surges up when a threat is detected. There is a readiness for emergency response, but from moment to moment life is not an emergency. This issue is revisited in the section on theoretical approaches.

Is there a gender difference in death anxiety? Women in the United States usually report higher levels of death anxiety than men. The few studies conducted in other nations find the same pattern. We can choose among several interpretations:

- Women are too anxious about death.
- Men are not anxious enough about death.

- There is no actual difference in level of death anxiety between the sexes, but women are more willing to acknowledge and express their concerns.

In weighing these alternative interpretations, it is useful to recognize the exceptional contribution made by women in providing care and comfort to dying people and their families. Much of the leadership and manpower in the international hospice movement has come from women, who also are far more likely than men to enroll in death education courses. Women have generally been more responsive to the needs of people with life-threatening conditions and more cognizant and accepting of their own feelings about death. Men generally seem more guarded and uncomfortable when circumstances remind them of their vulnerability. These gender differences have been related to childhood socialization patterns in which the expression of feelings, especially those of vulnerability, is encouraged in girls but discouraged in boys.

Women may be too anxious about death if the criterion is subjective comfort, but men may be not anxious enough if the criterion is the readiness to respond to the mortal jeopardy of self and others. Research also suggests gender differences in the type of situations that arouse the most anxiety. Men express more fear of extinction and the way their post-death self will be remembered. Women express more fear of the dying process and of being unable to make adequate arrangements for the well-being of their families. These differences should not be overestimated. There are marked individual differences in personality within each gender.

Is there an age difference in death anxiety? Do we become more anxious as we grow older because of the decreasing distance from death? Or do we become less anxious because we develop a more mature outlook on life and death?

Age differences, when found, indicate less fear of death among elderly people. Concerns are more likely to center around the challenges and stresses of daily life, such as protecting relationships and self-esteem. However, it should be kept in mind that each generation passes through unique historical circumstances with distinctive configurations of social attitudes, economic up- and downturns, technological innovations, and threats to life. The fact that most elders have been reporting low or moderate levels of death anxiety probably represents the interaction of their distinctive life histories and current health and socioeconomic status, as well as their personal accommodations to the aging process. Qualitative studies have identified specific concerns that are most salient for

people at different points in their life course. Young people seem most apprehensive about the possible loss of loved ones, death as punishment, and the finality of death. Midlife adults express most concern about premature death and fear of pain in dying. Older adults do not fear death as much as they do the prospect of becoming helpless and dependent on others during their final phase of life.

There is little support for the hypothesis that people become more anxious as the distance from death decreases with advanced age. Self-actualization and existential theories propose that acceptance of death is a mark of maturity. This is an attractive proposition, but not an established fact. It might be overreaching to insist that philosophical acceptance of death is the only way a mature person can come to terms with mortality. Furthermore, other explanations might account for the relatively low death anxiety found among elderly adults. Some people experiencing social isolation, financial concern, and age-related physical problems express a readiness to have their lives come to an end – an attitude that is also reflected in the high completed suicide rates for elderly white men. Low death anxiety might then be related to dissatisfaction with a life that is no longer considered worth living.

What are the demographics of death anxiety? People in favorable socioeconomic circumstances tend to report lower levels of death anxiety. Education, affluence, and status serve as buffers against death anxiety (though not impenetrable buffers). Growing up in an intact family and having a secure interpersonal environment also offer some protection against high death anxiety. Married people generally live longer and are less likely to commit suicide. We might therefore expect that married people would experience less anxiety than those who are single or divorced, but, surprisingly, this proposition has not been systematically examined.

Religious beliefs and practices have a complex relationship with death anxiety. Anthropologists and historians have argued that religion originated as a response to the fear of death. A particular religion operating within a particular cultural context might be effective in controlling death anxiety with comforting rites of passage and images of blessings in the afterlife. The opposite effect is also possible, however. Presenting death in frightening images is an effective way of keeping anxiety bubbling and therefore motivating people to seek protection by obedience to the establishment. In today's mass and heterogeneous societies, religion offers a broad array of beliefs and practices, some of which seem likely to reduce and others to increase death anxiety. Some people of faith

might have less fear of death because they expect a joyful afterlife, while others are beset by anxiety about damnation. Surveys continue to indicate that most people in the United States do believe in an afterlife. Studies of terminally ill people suggest that there is more anxiety about suffering and dependency during the dying process than fear of death as such. Religious faith and belief in an afterlife seem to help many people face the prospect of death, but they are still vulnerable to anxiety about the dying process and the effects of their death on others. It has become clear, however, that many people feel more secure during their final illnesses when they know that they will be given full benefit of the religious and social customs that are meaningful within their group.

What are the personality and lifestyle correlates of death anxiety? People who are afflicted with many other fears are likely to have relatively high death anxiety as well. People with humorless authoritarian personalities are the least likely to sign the organ donation forms attached to their drivers' licenses, suggesting a higher level of death-related anxiety. A dominating need to control situations and to win at all costs has been related to a feeling of vulnerability: catastrophic anxiety and death must be warded off by exercising power over the course of events. Similarly, some people who seem to live outside of themselves through causes and cults do so to achieve a sense of participatory immortality and thereby escape the sting of death anxiety. By contrast, people with deep interpersonal attachments who have a strong sense of purpose in life tend to have a lower level of death anxiety.

Death Anxiety in Particular Situations

Our focus now shifts from characteristics of the individual to the types of situations in which individuals may find themselves. We draw now upon a wide range of observations beyond self-report questionnaires.

Transitional situations We often experience heightened death anxiety in transitional situations. Starting or losing a job and moving to a new community are common examples of transitions that have no evident relationship with death but that can engage feelings of uncertainty and threat. Separation, divorce, and other significant changes in relationships can also arouse a sense of vulnerability, which, on the emotional map, is not far from fear of mortality. Even detection of the first gray hair can trigger the recognition that one is no longer young, thereby arousing the lurking fears of aging and death. Determined attempts to look young often express a convergence

of fears: "I will be less attractive, less valued, less useful – and I will become the sort of person who is most likely to die – the old-timer."

The community at large can also experience heightened stress during periods of transition and uncertainty. Apprehension about unemployment, inflation, inadequate health-care benefits, and difficulties in coping with bureaucracy and technology can all contribute to a sense of helplessness, which, in turn, increases permeability to awareness of mortality. A society that has lost confidence in its purpose and competence may contribute to heightened death anxiety throughout all ages, ranks, and echelons.

Touched by death Exposure to death does not always make us anxious. Sometimes we seal off such episodes quickly before they can penetrate our awareness. At the extreme, we may deny the significance of the event, as when the victim of a heart attack insists that he is just fine and does not need medical attention. More often, though, we use subtle defensive strategies to avoid the impact of an exposure to death. For example, at a funeral we may not permit ourselves to acknowledge a possible resonance between the neighbor who died of pulmonary disease and our own habit of smoking. "It's too bad about the neighbor, but I don't smoke the same brand of cigarettes." Many of us are gifted in the ability to shed exposures to death in order to preserve the comforting routines of everyday life. Nevertheless, some exposures to death do get through to us. Usually these exposures take one of two forms: a personal brush with death or the death of another person.

It is not uncommon for the stress reaction to develop after a life-threatening emergency. A competent driver or pilot, for example, is likely to respond to an emergency with quick and skillful actions. Only when the danger has passed will the emotional reaction seize its opportunity, perhaps taking the form of a transient posttraumatic stress episode. Anxiety aroused due to a close call with death usually dissipates quickly, although there may be heightened sensitivity to future risk situations. What has become known as a near-death experience (NDE) is a different case. These episodes almost invariably involve risk to life that the individual could not deal with through personal initiative and action (e.g., the passenger in a car hit in a broadside collision). The NDE is an episode split off from the person's usual life and marked by unusual, dream-like events. Instead of intense anxiety, however, many reports depict a remarkable feeling of serenity and liberation. Some people believe that they not only have been touched by death but also were actually in death for a short period of time. There are varying interpretations of

the actual state of being during a NDE, but a great many reports that anxiety about death completely dissipated after the experience.

By contrast, the death of another person is often mentioned as the wake-up call that leads to anxious realization of one's own mortality. Most often it is the death of a parent that produces an increased sense of personal vulnerability. "Death is coming after me, now!" as a 50-ish woman exclaimed after the death of her mother. The death of a long-lived cultural icon can also lead to feelings of vulnerability and abandonment. In addition, we are likely to experience an upsurge of death-related anxiety when a person seen as much like ourselves passes away. Our behavior toward others when they are terminally ill and during the funeral process can be markedly influenced by anxieties aroused by our feeling that "this could be happening to me."

Facing death: Life-threatening illness The prospect of our own death may flash before us in a quickly developing episode as already noted. It is a different matter, however, when the threat is persistent, as in the case of life-threatening illness. Coping with a threat to life varies with both the individual and the medical condition (e.g., a cardiac disorder that might end one's life at any time or advanced pulmonary disease in which every breath is a struggle as the disease continually progresses). Nevertheless, there are also some common issues that often intensify anxiety. These include (a) uncertainty about diagnosis and prognosis, (b) learning that one has a life-threatening condition, (c) progression of symptoms and dysfunctions that suggest that treatment efforts are failing, (d) interpersonal cues that others also recognize the end is approaching, along with concern about losing one's most valued relationships, (e) concern about practical end-of-life matters, (f) concern about the overall meaning of one's life, and (g) anxiety about experiencing helplessness and pain in the end phase of the dying process. Patients often are aware of the anxiety that exists in others around them: it has been found that physicians often experience intense discomfort in the terminal-care situation and therefore try to limit their contacts with the patients. It is not unusual for death anxiety to be reinforced and multiplied throughout the entire terminal-care interpersonal network.

There is some evidence to suggest that episodes of intense anxiety can trigger sudden death in people with coronary heart disease. These findings support earlier observations that a person literally can be scared to death. However, a moderate level of anxiety might be more protective than a denial reaction. It has

often been suggested, but not yet firmly established, that high levels of anxiety can also increase the risk of death in other life-threatening conditions.

Anxiety peaks most often at two points. The first jolt usually occurs when the person discovers that his or her illness is terminal. Suicidal ideation can develop during this chaotic period of panic and depression. Trustworthy and sensitive communication on the part of family and health-care providers can prevent a plunge into the depths of despair or an anxious leap into self-destruction. The second anxiety peak, again accompanied by depression, arises as a result of continued physical deterioration, fatigue, and apprehension regarding progressive loss of function. "I'm just so tired of dying" is how more than one person has expressed it. Here anxiety is focused less on death than on the fear of being abandoned and isolated while continuing to suffer for no good reason that the person can see. Euthanasia is not sought by all people in the end-phase of their terminal illnesses, however. Many continue to experience life as meaningful and to be protected from disabling anxiety by positive belief systems and loving support from the people most important to them.

Anxiety and depression associated with terminal illness have often been the result of social isolation and inadequate control of pain and other symptoms. The pioneering contributions of Elisabeth Kubler-Ross and Dame Cicely Saunders have done much to improve this situation. Kubler-Ross, a psychiatrist, encouraged professional and family caregivers to overcome their own anxieties about interacting with terminally ill people. Saunders, a nurse and physician, launched and guided the international hospice movement that provides a broad spectrum of symptom relief with a combination of compassionate care and palliative expertise. As their own lives neared the end, Kubler-Ross and Saunders both received the benefits of the hospice care they had helped make possible for people around the world. Recently, the medical establishment has shown signs of agreeing with the hospice premise that pain should be regarded as one of the vital signs to be assessed and effectively treated in all physician-patient interactions. Team approaches to the comfort of terminally ill people and their families with priorities given to the dying person's own lifestyle and values have also contributed to reducing anxiety throughout the final phase of life.

Major mental health problems People who feel that their worlds are exploding or collapsing often express intense anxiety about death. Some of the most striking expressions of death anxiety are found during psychotic episodes, whether functional or triggered

by a drug-altered state of mind. Whatever the specific cause, it is usually the sense of losing total control over one's life that has precipitated the episode. Dying and death become metaphorical expressions of this panic. Severely depressed people may even present themselves as dead, thereby having passed beyond the reach of death anxiety. Helpful interventions include providing a higher degree of stability and simplicity in the sociophysical environment and creating situations in which the individual can begin to experience again a sense of competence and control. Approaches as different as expressive and drug therapies can also be useful.

Theories of Death Anxiety

General theories of stress and anxiety have potential for contributing to the understanding of death-related concerns. Here we focus on theories that were intended specifically for comprehension of death anxiety.

Freud and Becker: Rival Theories

Two theories may be considered classic for their bold positions and widespread influence. These views could not be more opposed in their fundamental propositions, although there are commonalities as well.

Sigmund Freud held that we cannot truly have a fear of death because we cannot believe in our own death. Notice that person who is standing off to the side and viewing your death – it is you, the spectator self who is still very much alive. Personal death is not comprehended by the foundational logic of our unconscious processes, while on the conscious level, we have not actually experienced death. An expressed fear of death (thanatophobia), then, is a phobic symptom that conceals the actual, deeper source of anxiety lodged in childhood experiences and stimulated by current life developments. This influential view relegated death anxiety to a derived, secondary status and thereby not of much interest in its own right. Later in his own pained and stressful life, Freud came to see dying and death as issues very much deserving of attention, but it was his earlier formulation that continued to prevail.

Ernest Becker challenged Freud's interpretation from an existential standpoint. For Becker, all anxiety is an expression of death anxiety. Our core fear of nonbeing attaches itself to an almost infinite variety of situations and symbols. This is where society comes in – it exists largely to protect us from being consumed by death anxiety. Becker charges that our language and customs are designed to disconnect us from ontological encounters with mortality. Even our

technologically resplendent civilization remains basically a theatrical performance piece to which we all contribute our talents and suspension of disbelief. We agree not to notice that we all happen to be mortal. The person who really believes in death – and is therefore really anxious about it – is often the person we call schizophrenic. Being normal means being fairly successful in protecting ourselves against facing up to reality.

Both the Freudian/psychoanalytic and the Becker/existential theories have served as useful guides to observation and reflection. Different as they are, however, both share the premise of universal application and the flaw of unverifiability. There are situations in which one theory or the other seems applicable, but also situations in which neither seem sufficient.

Emerging Theories

Several new theories have emerged, each offering a distinctive perspective and drawing upon a distinctive realm of empirical research. Terror management theory is an empirically oriented offshoot of Becker's position. Its core proposition is that self-esteem and a positive worldview serve as effective barriers to death anxiety. When we feel ourselves imperiled, we can call upon our sense of self-worth and confidence as well as our belief that our society is basically sound and the universe a friendly place in which to dwell. Whatever contributes to growth of self-esteem and confidence and whatever contributes to the moral character and resilience of society can stand between ourselves and mortal terror.

Developmental learning theory places death anxiety within the mainstream of sociobehavioral research. We learn to fear, avoid, or cope with death-related phenomena just as we learn to deal with all other life challenges: through a long process of maturation and social interaction. It is not necessary to assert either that all anxiety or no anxiety is related to death or that we all have some kind of fixed response to death-linked situations and symbols. As a society and as individuals, the shape and intensity of our anxieties and coping strategies are pretty much in our own hands, and are likely to vary from generation to generation.

Edge theory shifts the emphasis from fear of death to the readiness to respond to threats to life. Two frequently held assumptions are set aside. First, the question of whether or not we can truly comprehend death is not as important as it once seemed. The point is that we do recognize threats to survival, whether of ourselves or of others. A vigilance function is with us from birth. Like other living creatures, we are equipped with the ability to detect serious threats

and go on alert. The second assumption set aside is that we try desperately to hide our intense anxieties about death from ourselves and others. According to edge theory, however, we do not carry about a burden of repressed death anxiety. Instead, our moderate everyday approach to life is occasionally challenged by a potentially dangerous situation. We have a momentary sense of being on the edge of nonbeing. In such situations we go on alert and try to identify the source of the danger. If we can then either dismiss or take action to overcome the threat we experience only a sense of heightened activation. It is when we feel on the edge and cannot respond to the threat that are likely to be flooded by death anxiety.

Points of difference aside, current research and theory suggest that the understanding of stress management throughout life requires attention to the ways in which we come to terms with our mortality.

Defensive Behaviors and the Stimuli That Elicit Them

Across-Species Generality

Defensive Behaviors as Independent Biobehavioral Systems

Acute versus Chronic Behavioral Defenses

Defensive Behaviors, Stress, and Psychopathology

Glossary

Chronic mild stress (CMS)

A pattern of anhedonia involving reduced positive response toward normally rewarding items, such as a sweetened liquid or intracranial stimulation in reward sites, following intermittent exposure to a variety of mildly stressing stimuli or events. These behavioral outcomes, like those of both learned helplessness and subordination, have been shown to be responsive to antidepressant drugs. An array of evolved behavioral responses (e.g., flight or freezing) to threat stimuli such as predators or attacking conspecifics. Individual defensive behaviors are

Defensive behavior

	modulated by features of both the threat stimulus and the situation in which they are encountered. Many defensive behaviors are relatively consistent across mammalian species and may be a component of stress- or defense-related psychopathologies.
<i>Defensive threat/attack</i>	Display of weapons (e.g., teeth and claws) and strength (e.g., through loud vocalization) in response to close contact by an attacker, followed by bites or blows to particularly vulnerable sites on the attacker's body (typically, face and eyes).
<i>Dominance/subordination</i>	A pattern of relationships between a consistent winner (dominant) and a consistent loser (subordinate) in agonistic encounters. Both dominant and subordinate often show behavioral and physiological signs of stress, but these may be modulated by compensatory mechanisms in the dominant that are not available to the subordinate. Subordination has been used as a model of chronic social stress.
<i>Learned helplessness (LH)</i>	A pattern of reduced learning, particularly in active avoidance situations and of reduced activity in a threat context, following exposure to uncontrollable aversive events. This, like the chronic mild stress paradigm, has been proposed as a model of depression.
<i>Offensive attack</i>	An attack, typically (but not always) toward conspecifics, in the context of a dispute over important resources such as territory, access to mates, or food. An offensive attack is aimed toward species-typical sites on the opponent, often areas in which bites or blows do little serious damage. In contrast to defensive threat/attack, fear reduces offensive attack.
<i>Risk assessment</i>	A pattern of orientation, attention, and exploration with regard to potential threat stimuli, enabling an animal to gather information about their location, identity, and threat status. This information facilitates an optimally adaptive response to a genuine threat or promotes a return to nondefensive behavior if no threat is present.

Defensive behaviors are those activities that occur in response to the host of life-threatening dangers encountered in every natural environment, from predators, from conspecific attack, and from threatening features of the environment. They constitute the behavioral component of the stress response and have evolved on the basis that, to particular types of threat

stimuli and in particular situations, each such behavior has proved to be optimally adaptive in terms of enhancing the extended reproductive success of the individual. These behaviors range from active investigation of threat stimuli to actions facilitating escape from or termination of threat. Because the extended reproductive success of females may, in an important way reflect the survival of offspring in their care, the optimal defensive behaviors for males and females may differ: The magnitude and mechanisms of gender difference in defense are poorly understood, but there is speculation that these may be related to the substantial and consistent differences in vulnerability to particular psychiatric disorders for men and women.

Defensive Behaviors and the Stimuli That Elicit Them

Much recent work on defensive behaviors has focused on response to predators or attacking conspecifics, threat stimuli (especially the former) that elicit a number of defensive behaviors in rodents without the necessity of pain or prior experience. Although the defensive behaviors of higher primates are undoubtedly more complex than those of rodents and may involve some specific learning components, there appears to be an essential continuity of defense patterns across mammals such that research on the behavioral, neural, and neurochemical aspects of the defense systems may be very relevant to analysis of defense-related behaviors, including psychopathologies, in people.

Defensive behaviors are modulated by features of both the threat stimulus and the situation in which it is presented). The major (self-)defensive behaviors are:

1. *Flight* from the threatening stimulus, and avoidance of that stimulus if it is at a distance. These behaviors are facilitated by the presence of an escape route or a place of concealment and are dominant responses to high-level threat when such features are available.

2. *Freezing* when no escape route or place of concealment is available. Freezing involves orientation toward the threat source and immobility in a species-typical posture. Like flight, it increases in intensity as the threat approaches, up to a level of proximity that elicits defensive threat/attack.

3. *Defensive threat* occurs as the threat stimulus nears the subject. It consists of a weapons display (teeth bared, claws unsheathed) and loud sonic vocalizations such as screams.

4. *Defensive attack* occurs at even shorter threat-subject distances. This attack is often oriented toward

particularly vulnerable sites such as the predator/attacker's face and eyes.

5. *Risk assessment* occurs when the threat is potential rather than present (e.g., predator odor or novel situation) or of low intensity and includes sensory sampling (visual/auditory scanning, sniffing) and approach and investigation of the threat source, alternating with rapid retreat. Risk assessment is associated with low-profile postures and rapid movement interspersed with periods of immobility; these reduce the likelihood of detection as the animal approaches and investigates the threat stimulus. These activities enable the gathering of information, facilitating identification and localization of the threat source. If it proves to be a real danger, defenses such as flight or defensive threat/attack ensue. Alternatively, if risk assessment permits a determination that the situation is safe, then the animal can resume its normal activities (food gathering, self-care, or offspring care, etc.).

6. *Alarm vocalizations* occur in many (perhaps most) mammalian species with a colonial lifestyle. Such cries warn other group members of the appearance of a predator. In some primate species, different types of predator (e.g., terrestrial vs. aerial) elicit different alarm cries, permitting the listener to take defensive action appropriate to that predator.

These defensive behaviors all occur in the context of physical threat. Threat to resources elicits a very different behavior, offensive attack or aggression, which has a much weaker association with fearfulness or psychological stress. Both offensive and defensive (i.e., self-defensive) attack toward conspecifics in mammals tend to be oriented toward specific areas on the body of the opponent, and these target sites may provide an additional means of differentiating offensive and defensive attack modes. The former tends to be aimed at sites where bites or blows will produce pain without a high risk of damage to vital organs, whereas the latter is typically targeted toward the face of the threatener. This, for both conspecific and predator attackers, is both the site of particularly vulnerable and important organs, such as the eyes, and of the major offensive weapons of many animals, that is, the teeth. Because conspecific attack is so precisely targeted, an additional group of defenses against conspecific threat involves concealment of these especially likely targets of attack. These target-protection defenses, in combination with attacker behaviors that seek to thwart the defender (target concealment) strategy and reach the preferred attack target, may give fighting among conspecific mammals a dancelike quality in which the actions of one animal are immediately countered by appropriate actions of the other.

All of these defensive behaviors involve a strong component of orientation toward (or, in the case of flight, away from) the threat stimulus. In contrast, analyses of chronic internal pain (a stressful event not involving an external stimulus) suggest that the behavioral defense to this may be quiescence, involving reduced activity and inattention to external stimuli.

Across-Species Generality

These defensive behaviors and their specific associations with particular elements of the threat stimulus and the environment in which it is encountered show a high degree of cross-species generality in mammals. The generality is probably not limited to mammals, but mammals do appear to rely more strongly on this range of behavioral defenses than do other animals. Structural defenses (e.g., armor, venom, and poisonous tissues) and cryptic coloration are emphasized in lower vertebrates and invertebrates, whereas birds show an obvious specialization toward flight.

The behavioral repertory, including defensive behavior, of higher primates is more varied and sophisticated than that of more primitive mammals (e.g., rodents). However, the same defensive behaviors noted for rodents also occur in primates, albeit with greater elaboration of cognitive and communicatory elements. Examples are threat-differentiated alarm vocalizations, social or observational learning of threat stimuli (based on the defensive behaviors of conspecifics to these stimuli), and the formation of conspecific coalitions involving mutual defense and protection. Studies of defensive behaviors in humans are necessarily more indirect. However, choices of responses to scenarios designed to focus on features of the threat stimulus and the situation in which it is encountered strongly suggest that the relationship between stimulus/situational features and particular defenses in humans are broadly similar to those described in nonhuman animals.

Defensive Behaviors as Independent Biobehavioral Systems

Much classic research on defensive behavior had an initial "site" focus, in that it involved attempts to describe the immediate response of an animal to electrical or chemical stimulation of particular brain structures. Although a number of forebrain sites yield behaviors (e.g., vocalizations) that appear to be related to defensiveness, the most thoroughly investigated area has been the periaqueductal gray (PAG) region of the midbrain. This contains a number

of longitudinally coursing columns in which stimulation can produce defensive threat/attack, flight, and freezing or quiescence. Some controversy surrounds the interpretation of stimulation of the ventral PAG column in terms of the last two alternatives. Responses related to defensive threat appear to be more common in the anterior components of these systems, whereas flight and freezing occur with stimulation in more posterior sites. It is particularly interesting that the PAG has been mapped in both cats and rats and that the specific areas where particular behaviors are elicited by stimulation appear to be very consistent.

Typically such studies did not provide a strong threat stimulus, or even an opponent to which the animal could orient and react, making interpretations of behavior more difficult. More recent attempts to determine the neural systems of defense have involved specific stimuli, notably presentation of a cat or cat odor to the subject rat. These studies indicate that cat stimuli elicit a strong c-Fos expression in specific areas of the amygdala, lateral septum, and specific nuclei of the hypothalamus, notably the dorsal pre-mammillary nucleus. Lesions of the last of these strongly reduce responsivity to a cat or cat odor, but do not have a major impact on freezing following foot shock, suggesting considerable stimulus or stimulus modality specificity of control of defense in some forebrain structures. In addition to anatomical differences, there appear to be differences in the neurochemistry of the biobehavioral defensive systems, providing a basis for findings of differential response of these systems to psychoactive drugs.

Acute versus Chronic Behavioral Defenses

In addition to acute exposure paradigms, a number of models of chronic social or predator threat have been devised and used to evaluate behavioral and physiological effects of longer-term stress. In a particularly desirable habitat, with females and a burrow system, male rodents quickly create a strong dominance hierarchy based on victory and defeat. Defeated subordinate male rats spend most of their time within a particular chamber or tunnel, from which they attempt to exclude the victorious male (dominant); defensive threat/attack is a particularly effective defense in a tunnel. From these sites, subordinates also consistently monitor the dominant's location, avoiding the surface area when it is present and fleeing when they are in the open area and the dominant appears. Subordinates spend most of their waking time in defensive behavior and lose weight even when food and water are freely available.

Much of the defensive behavior of a subordinate rat to a dominant is very similar to that seen on initial exposure to a threat stimulus, except that it is more protracted. However, prolonged exposure to threat/stress may produce deleterious behavioral changes such as reduced activity, a shift away from active defense toward more passive defenses, and possibly a shift to a quiescent state in which the animal becomes less, or less effectively, attentive to possible environmental dangers. In learning situations, particularly those involving an active avoidance response, deficits in responding by animals chronically exposed to an uncontrollable stressor are characterized as indicating LH. A potentially similar phenomenon in subordinate rats involves greatly prolonged risk assessment without transition to nondefensive behavior. This may also reflect a learning deficit and it, like the active avoidance deficit of LH rats, may be quite maladaptive. The prolonged (and often inadequately cautious) risk assessment behavior exposes the animal to danger if a threat is present, whereas the failure to resume normal behavior patterns is maladaptive if there is no threat present.

Another behavior associated with chronic stress (in a CMS model) is anhedonia, typically indexed by reduced consumption of sweetened liquids. In fact, the CMS animals may actually show heightened preference for more intensely sweetened liquids.

Defensive Behaviors, Stress, and Psychopathology

Defensive behaviors – both those seen in response to acute threat and the altered patterns expressed after chronic threat/stress – have many parallels to the behavioral components of a range of human psychopathologies. In particular, risk-assessment behaviors appear to be very similar to the increased vigilance and scanning characteristic of generalized anxiety disorder, whereas reduced activity, anhedonia, and deficits in active avoidance learning have parallels in depression.

An additional parallel between the chronic stress models and depression is through alterations in the functioning of the hypothalamic-pituitary-adrenal (HPA) axis and changes in brain neurotransmitter systems. Different physiological systems have often been emphasized in investigations of the various chronic stress models (LH, CMS, and subordination), and so a consensus on their commonality of effects is difficult to obtain. HPA axis changes appear to be most severe for subordinates, many of whom show greatly decreased levels of corticosterone binding globulin, reduced corticosterone (CORT) response to acute stress, and reduced corticotropin-releasing

factor (CRF) in the paraventricular nuclei of the hypothalamus, indicating the involvement of brain mechanisms in this deficit. Subordinates also show sharply reduced levels of testosterone, reflecting both peripheral and central effects of stress, with the former appearing prior to the latter. For the most part, LH is not associated with these hormonal effects, particularly when the criterion of experiencing uncontrollable versus controllable shock is applied. This very stringent criterion, using chronic but controllable shock as a control condition, may obscure some important changes in stress-linked physiological systems. As befits the term chronic mild stress, the CMS model also fails to produce notable hormonal changes. However, all three models have been associated with brain neurochemical changes, particularly involving biogenic amines, and a number of these brain changes, as well as the behaviors with which the models are associated, have been shown to be reversible after treatment with antidepressants. These hormonal and brain effects, in addition to the changes in defense and other behaviors after chronic stress, suggest that animal models of chronic stress may provide some very relevant analogs to depression and further emphasize the potential value of use of these behaviors as pre-clinical models for research on the pharmacology of emotion-linked disorders.

This approach has produced many interesting results. Risk-assessment behaviors show a selective response to anxiolytic drugs such as classic benzodiazepines. Antipanic drugs (e.g., alprazolam, imipramine, fluoxetine, and phenelzine) decrease flight behaviors, whereas the panicogenic agent yohimbine increases flight. As with clinical findings, the effects of these antipanic drugs on flight require chronic administration, whereas the initial injection of imipramine and fluoxetine may actually exacerbate defense. Both CMS and LH models have proved to be responsive to a variety of antidepressant drugs. However, the various behavioral effects of the latter model, such as reduced activity and disrupted learning of an active avoidance response, may show differential patterns of response to antidepressant and anxiolytic drugs. Both acute and chronic social defeat produce behavior changes that are normalized by fluoxetine, a selective serotonin reuptake inhibitor that has antidepressant as well as antipanic effects. In general, these findings suggest that, although acute and chronic stress may

produce a wide pattern of changes in defensive and other behaviors, it is the behavioral response itself, rather than the stress paradigm, that may provide the clearest and most direct relationship to particular stress-linked psychopathologies.

Glossary

<i>Decision authority</i>	The component of decision latitude that is the possibility for employees to influence how to do work.
<i>Decision latitude</i>	The possibility for employees to influence decisions regarding work.
<i>Iso-strain</i>	The combination of high psychological demands, poor decision latitude, and poor social support at work.
<i>Job strain</i>	The combination of high psychological demands and poor decision latitude at work.
<i>Skill discretion</i>	The component of decision latitude that is the possibility for employees to develop skills at work (improving possibility to make decisions); also called intellectual discretion.
<i>Work social support</i>	Support from workmates and superiors.

History

The demand–control–support model was introduced in the early 1970s by Karasek in his doctoral thesis and published internationally in 1979. It was further developed in relation to psychophysiological theory and empirically tested in relation to cardiovascular disease by Karasek and Theorell during the 1980s. The support dimension was tested and discussed in more detail for the first time in 1990 by Johnson and Hall. The demand–control theory states that the combination of high psychological demands and low decision latitude (job strain) is particularly dangerous

to health. The demand–control–support model states that the effects of job strain are worsened by poor social support and ameliorated by good social support; on the other hand, high demands with high decision latitude (active work) may be associated with psychosocial growth and improved coping.

The demand–control model is related to the general stress theory of Selye (demands) and to the sociological alienation theory of Gardell. Karasek combined these two theories into a two-dimensional environmental theory. When the two dimensions are combined with the support dimension, a three-dimensional model arises (see [Figure 1](#)). The ideal situation is a job without excessive psychological demands in which the employees have good decision latitude and good support (relaxed with good support). The worst situation is a job situation with high psychological demands in which employees have low decision latitude and poor support (high strain with poor social support or iso-strain). According to the theory, all the other situations – high demands and good decision latitude, active with good and poor social support, and low demands and poor decision latitude, passive with good and poor social support – occupy intermediate positions with regard to illness risk and health.

Frankenhaeuser had earlier described another two-dimensional model focused on the individual's reaction to stressors. When the effort dimension is combined with the joy/uneasiness dimension in the reaction, it becomes evident that a high degree of effort may be combined either with joy (eustress) or with uneasiness (distress). This model has a similarity with the demand–control model, but the demand–control model is an environmental model, whereas the Frankenhaeuser model is an individual-reaction model. This means, for instance, that individual distress reactions are more common in high strain and eustress reactions more common in active work.

Later, the Frankenhaeuser and the demand–control models were incorporated into other models. Examples are the effort–reward imbalance model (see [Effort-Reward Imbalance Model](#)) and the demands–resources model. In the latter model, resources include personal resources as well as external ones such as decision latitude and social support.

The Model and Its Components

Decision latitude (DL) is defined as possibility for the individual employee to exert control over his or

Figure 1 A three-dimensional model of the psychosocial work environment. From Karasek, R. A. and Theorell, T. (1990) *Healthy work*, New York: Basic Books.

her work situation; it does not refer primarily to the individual's ability to exert control because the focus in the demand-control-support model is on the organization's demands on the employee and the possibility that it gives control to the employee to handle these demands. DL has two components: decision authority and skill discretion. Both of these components are related to the exertion of control. Decision authority is the influence that the employee has over how the work is done (control over tasks). Questions regarding decision authority typically deal with influence on tempo and production techniques and whether employees have any say in decision making. Skill discretion is the development of competence and skills (control over knowledge). Typical questions regarding skill discretion deal with the possibility of learning new things, variations, and skill requirements.

Psychological demands in the demand-control model correspond to several kinds of external demands in the work situation. They are added up to produce a total score. It has been pointed out in recent discussions that this assessment practice may create problems. For instance, long working hours and high intensity should perhaps be treated as separate variables because they are patterned differently in different social groups and occupational branches. Similarly, emotional and cognitive demands are different. Social support refers to emotional as well as instrumental support from both superiors and work-mates. The three basic dimensions – psychological demands, decision latitude, and social support – are

assessed using many different questionnaires; the most widely used questionnaire for the assessment of the total model is Karasek and colleagues' Job Content Questionnaire (JCQ).

The Model in Relation to Heart Disease

There is a growing body of research showing that the demand-control-support model is related to heart disease risk. Most of the empirical studies have been performed on demands and decision latitude. That poor social support contributes to cardiovascular mortality, however, was shown in a 1989 prospective study of the Swedish working population that showed that a combined self-rated measure of iso-strain was associated with a 9-year excess risk of cardiovascular mortality in men in the upper tertile of job strain, compared to those in the lowest tertile (relative risk of dying 1.77, with 95% confidence interval 1.28–2.44). Reviews of the demand-control model have been published, for instance, by Belkic and colleagues, who performed a methodological analysis of the sources of error and strengths in published studies. Their conclusion was that there is convincing evidence that job strain is a risk factor for cardiovascular disease.

There have also been prospective studies, however, with negative findings. One possible explanation for the discrepancy in findings is the age factor because the negative studies have mainly been long-term follow-up studies of relatively old employees. When a large proportion of the participants in a study are relatively old, they may retire during the follow-up

period, and it has been shown that the effect of exposure to job strain diminishes after retirement. A prospective European study by Kornitzer and colleagues with a 5-year follow-up of 20,435 middle-age men previously free from coronary heart disease has recently been made. One hundred and eighty of these men had myocardial infarctions during follow-up. When comparisons were made with the relaxed group, there was clearly an excess risk of myocardial infarction in the job strain group (after adjustments odds ratio 1.5, with 95% confidence limits 1.0–2.3) but not in the active or passive groups.

In prospective cohort studies with full control of retirements, clear associations have been shown. For instance, in the 2002 Finnish Valmet study, the excess cardiovascular mortality risk during follow-up was 2.2-fold (95% confidence interval 1.2–4.2) after adjustments for other risk factors.

The findings for women have been less consistent than findings for men. It has been argued that the demand-control model may be less relevant for women than for men. This could be true. However, direct comparisons between men and women are difficult because of the smaller female samples and because in several countries women work part-time more often than men.

Demand-Control and Effort-Reward: Independent Predictions?

Two studies of cardiovascular disease, the 1998 prospective Whitehall II study and the 2004 Stockholm SHEEP study have used the effort-reward imbalance (see **Effort-Reward Imbalance Model**) and the demand-control models together, and the findings indicated that they predict coronary heart disease episodes partly independently of one another. In the Whitehall II study of British civil servants, the decision authority component of the demand-control model and the effort-reward imbalance model both made independent predictions of new episodes of coronary heart disease among previously healthy state employees. In the Stockholm SHEEP study, a large population-based case control study of first myocardial infarctions, self-rated job strain as well as the intrinsic and proxy measures of the extrinsic parts of the effort-reward model were studied as separate variables. The results showed different results for men and women. For men, a combination of job strain and imbalance between extrinsic effort and reward was the best predictor of myocardial infarction status. In women, the intrinsic part of the effort-reward model (overcommitment) had the same role as the extrinsic one did in men – a combination of overcommitment and job strain was the best predictor.

It is not known to what extent self-reported assessments of the psychosocial work environment (on which the majority of research reports have been based) reflect individual characteristics (which may distort the perception of reality) and to what extent they reflect true environmental conditions. Critics argue that subjectivity bias may explain most of the observed associations between the psychosocial work environment and coronary heart disease. The general impression, however, is that objective assessments of the demand-control-support dimensions predict in ways similar to the self-reported more subjective ratings, although the associations are attenuated.

In their study of imputed and self-reported assessments of demand and decision latitude in first myocardial infarction cases and referents (SHEEP), Theorell and colleagues showed that there was no evidence of recall bias (distortion that could cause false associations) for decision latitude self-reports in the myocardial infarction cases. The analysis of demands was more difficult because the relationship between self-reports and imputed scores was much weaker than for decision latitude.

Other Health Outcomes

Mental disease outcomes have also been studied in relation to the demand-control-support model. A prospective design seems to be particularly important when mental disease is studied because a slow onset of a mental disease could influence the work environment and the relationships could be affected by this. There are a few such published studies. Stansfeld and colleagues found in their follow-up of British civil servants that low decision latitude, high demands, and poor social support were all related to an elevated risk of development of new mental illnesses (defined as a bad score on the 30-question General Health Questionnaire). Niedhammer and colleagues reported similar findings on the development of new depressive symptoms during follow-up of a cohort of French workers (GAZEL study). All the three dimensions in the model – high demands, low decision latitude and poor support – were associated with a risk of development of depressive symptoms.

Findings with regard to musculoskeletal disorders have been more mixed in the literature. In most studies, at least one of the three dimensions has a relationship with the risk of developing musculoskeletal disorders. The psychosocial factors interact in complicated ways with physical demands, and there is a debate as to whether or not an adjustment should be made for physical demands when the association between psychosocial job factors and musculoskeletal disorders is studied. In addition, the relationships

seem to be different in different occupational groups, in men versus women, and in different cultural settings and for different diagnoses (low back pain and neck/shoulder pain, for instance).

Other illnesses have also been studied. For instance, Westerberg and Theorell showed that there is an association between low decision latitude and functional gastrointestinal disorder. In men, a follow-up of individuals with such episodes showed that in men (but not in women) good support from colleagues was associated with rapid recovery.

Physiological Mechanisms

The psychosocial work environment could influence illness risks either through influences on lifestyle factors such as cigarette smoking, physical activity, and eating habits or through more direct physiological mechanisms. A possible indirect way of studying the effect of the demand-control-support model on lifestyle factors is to explore the association among the model, cigarette smoking, and serum lipids. Such studies have shown that low decision latitude is related to a high prevalence of smoking and high serum lipids and that this association holds even after adjustment for social class and education.

Most researchers presently agree that all the association between job strain and risk for cardiovascular illness cannot be explained by lifestyle-related risk factors. Therefore, other mechanisms more directly related to biological stress reactions have been explored. Blood pressure variations measured automatically at repeated intervals during the 24-h circadian cycle have been related to job strain in several studies. A high systolic and diastolic blood pressure during work hours has been shown in job strain in several studies, and in some studies this elevation has extended also to leisure hours and to sleep. A high morning cortisol, especially half an hour after awakening, seems to be a characteristic of the job strain day. Recently, coagulation and inflammation parameters have been explored. Several studies have shown a relationship between job strain and/or low decision latitude and plasma fibrinogen, even after adjustment for other risk factors. Interleukins and other markers of inflammation are presently being studied. Longitudinal studies of variations in demands, decision latitude, and social support have been performed. These studies have shown that increasing job strain is associated with increasing systolic blood pressure, decreasing sleep quality, and, in men, lowered serum testosterone. Karasek and co-workers have started exploring the associations between intra-individual variations in decision latitude during the daily round of life and variations in autonomic indices as

they are reflected in 24-h recordings of heart-rate variability.

In summary, it is likely that the working conditions associated with job strain are associated with increased energy mobilization and decreased anabolism. Both of these processes may increase cardiovascular disease risk.

Childhood Confounding

Theoretically, there is a possibility that adverse material childhood circumstances (infections, nutrition, drinking water, etc.) could explain the relationship between psychosocial work conditions and coronary heart disease. The argument would be that subjects with a poor childhood are more likely than others to end up in bad jobs with poor psychosocial environments. Life course research is beginning to address these kinds of questions. For instance, in the Valmet study the prospective relationships between work stress and risk of cardiovascular death were adjusted for a number of childhood factors, and both job strain and effort-reward imbalance remained as significant predictors even after these adjustments.

Examples of Organizational Interventions in Workplaces Aiming at Decreased Heart Disease Risk

If low decision latitude, high demands, and poor social support contribute to health and disease, they represent conditions that could be the focus of interventions. For several reasons, the health effects of such interventions are difficult to evaluate. However, particularly in the Scandinavian setting, evaluations of the health effects of organizational changes aiming at improved worker participation have been made.

The Stockholm group has performed an intervention study aiming at improved psychosocial knowledge in managers. Managers in an insurance company had mandatory psychosocial education once every second week (a half an hour lecture and a 90-min group discussion) for a whole year. The education program comprised all relevant aspects of psychosocial working conditions, such as the role of demand, decision latitude, social support, and effort-reward imbalance. Their employees were examined before the study, after half a year, and after a whole year with regard to psychosocial work conditions and serum cortisol (when they arrived to the office in the morning). Employees in another comparable part of the same organization (with managers not subjected to the psychosocial training) were followed at the same intervals (130 subjects in each group). Whereas cortisol levels remained unchanged in the comparison

group, the employees in the intervention group had a substantial significant decrease in serum cortisol during the follow-up year. Psychosocial questionnaire data from the same groups of employees indicated that the development of decision authority was more favorable in the intervention group than in the control group, although demands and work pace developed in the same way in the two groups. These results indicate that managers could be one target group in psychosocial work-site interventions and that the improvement of decision authority for employees may be a crucial variable. Bond and Bunce published a British study in which three workplaces were randomly allocated to intervention and three similar workplaces were assigned to the control condition. The intervention followed the principles of participation activation research (PAR), which aims at improved employee participation in decisions at the workplace. A 1-year follow-up showed that the employees in the intervention group had lowered amounts of sick leave and improved self-ratings of performance and mental health. Such changes were not seen in the control group, and statistics showed that the improvement in employee participation accounted for nearly all of this.

In a psychosocial intervention program in Sweden, a similar strategy was used, which involved all the employees in the workplaces. Compared to the control group, the intervention group showed improved decision authority and improved lipoprotein patterns (which are associated with decreased cardiovascular risk).

Critique and Place of the Demand-Control-Support Model

There have been several criticisms of the demand-control-support model. We present the most important ones here.

Old Model in a Changing World

Society is changing, and the basic concepts in the demand-control-support model may not be as important as they were in the past. The model is 30 years old and was formulated on the basis of a society with a large industry sector dominated by production lines. It has turned out, however, that the model is applicable to most kinds of jobs in society.

Another argument is that it is possible that the increasing demands in people's work life that have been documented in North American and European work environment surveys during the 1990s and early 2000s will make the model invalid in the end. If demands are extreme in all parts of the work life, there will be no opportunity for employees to use

the decision latitude that they are given in the system. At least in European men, this had not happened during the latter half of the 1990s because the recent study by Kornitzer shows the same order of magnitude of excess myocardial infarction risk that was observed previously. For mental disorders, there are very few prospective studies, but the British Whitehall II follow-up study from the late 1990s and the French GAZEL study both show that the model is relevant for mental disease in both men and women during this period. It is true, however, that the world of work is constantly changing and that there is a need for new questions and new dimensions to be added. It has been pointed out, for instance, that the large changes on the company level that are becoming increasingly frequent belong to a high level of decision latitude that is not captured by the instruments that are presently used (control over). A concept that is related to decision latitude, justice, has recently been introduced in this research field.

A theoretical model has to achieve the right balance between generality and specificity. The model has been sufficiently general to generate theoretical interest but not so general that it is trivial. For practitioners exploring work-site conditions, it will never be enough to use general demand, decision latitude, and support questions. We have to formulate more specific questions for the individual work site as well.

Psychometric Difficulties

Although the three dimensions in the model mostly form distinct entities in factor analyses based on mixed working populations, they may still be psychometrically imprecise. The demand dimension contains emotional and quantitative demands, for instance. These kinds of demands may mean very different things in different groups. Decision latitude has two components that behave slightly differently in different populations. There has been a tendency among researchers during later years to focus on decision authority only rather than on decision latitude (the combination of skill discretion and decision authority). In social support, finally, there is support both from superiors and from workmates, and these components could also have differential impacts on health. Accordingly, there is more work to do in improving the instruments. Today there are many other sets of questionnaires that could be used in the assessment of demand, decision latitude, and support at work.

No True Interaction among the Components

The three dimensions in the model seem to operate relatively independently of one another. There are

very few published studies that have shown a true multiplicative interaction between demands and decision latitude in generating risk for illness. This is true, but the combination of high demands and low decision latitude has been a more precise risk indicator in most of the epidemiological studies than low decision latitude or high demands separately.

No Individual Component

The demand-control-support model has its focus on the environment, and its use has been intended to be a tool in the improvement of work design. Of course, the individual is also important in the pathogenesis of bad health. Assessments of the model components could certainly be supplemented by assessments on the individual level.

The demand-control-support model has been of great importance to the psychosocial work environment field because it has stimulated a large number of research projects and generated increased interest in job stress and illness during the past 15 years. It captures both negative and positive aspects and has great value in practical work at real work sites.

Introduction

Psychological Coupling of Mouth and Teeth
Dental Fear, Phobic Reactions, and Panic Disorder
Psychosomatic Manifestations in Dentistry
Prevention and Treatment Possibilities

Glossary

Biofeedback Use of sensors and instrumentation capable of detecting, amplifying, and displaying a function-relevant biological signal to achieve self-regulation of a given physiological function (e.g., muscle tonus in relaxation).

Conscious sedation Deep sedation for minor operative procedures in which the administered drug

(benzodiazepine) renders the patient calm, conscious, and cooperative; however, there is often total amnesia of the operation.

Denture intolerance

Appearance of psychogenic symptoms reported by the patient in relation to fixed or removable dentures or to the treatment procedure, with the absence of detectable pathological conditions of the related tissues and the absence of detectable insufficiency of the denture.

Mental hygiene

Interdisciplinary view of maintaining mental health and preventing mental sickness during all kinds of human services (e.g., medicine, dentistry, teaching, pastoral counseling, social work, justice).

Odontophobia

Phobic reactions related to dental treatment, the dentist, or the dental surgery office.

Oral stage

Highly important early phase of psychological development in which breastfeeding plays a prominent role in communication between mother and infant.

Orofacial

Localized in, or related to, the hard or soft tissues of the mouth, tongue, teeth, or face.

<i>Panic disorder</i>	Disorder with the symptom of recurrent intensive feelings of alarm linked with various bodily reactions and fear of death.
<i>Photoacoustic stimulation</i>	The simultaneous stimuli of flashing lights delivered through closed eyes and rhythmic noises.

Introduction

Stress-related problems in dentistry are a collection of various psychological conditions. The most common and widely known phenomenon is dental fear, which may lead to phobic reactions or panic attack in some cases. Another large group of stress-related reactions in dentistry is formed by several orofacial psychosomatic manifestations based on the rich psychological coupling of the mouth and teeth.

Psychological Coupling of Mouth and Teeth

The mouth and teeth are important aspects of an individual's facial aesthetics and sexual characteristics and play an important role in speech and meta-communication (beginning as early as the oral stage of infancy). The mouth, teeth, and tongue take part in sexual contact and act as organs of the senses of touch and taste, leading to a reach representation of these organs in the central nervous system. In addition, they have a strong symbolic meaning related to sexuality, strength, and aggressiveness. Tooth loss, especially edentulousness, symbolizes the loss of sexual characteristics and the living force and evokes a symbolic meaning of growing old, evanescence, and death. Another important psychosomatic coupling is that masticatory muscle tonus seems to be more strongly coupled to psychological stress than other muscles of the body; salivary secretion (including excretion of defense proteins such as secretory immunoglobulin A (sIgA) and the salivary chaperone Hsp70) is also well known to be strongly influenced by psychological stress. These multiple psychological couplings of the mouth, teeth, tongue, masticatory muscles, and saliva are responsible for the reach psychological phenomena appearing in the field of dentistry.

Dental Fear, Phobic Reactions, and Panic Disorder

Problems relating to dental fear primarily occur before the age of 20. Most patients suffering from dental fear experience at least partial remission at times, and a large proportion of these patients are

aware of having been exposed to fear-provoking dental treatment in the past. In some cases, an unconscious psychological trauma may also be a cause of such reactions. Patients with dental fear, including patients having phobic reactions (odontophobia), are usually agreeable to using medications and/or several psychological techniques to reduce fear during dental treatment. Patients with panic disorder and patients fearing injections (needle phobia) are exceptions, however, because they usually recognize their indisposition (usually simple collapse or panic attack) as a result of a supposed life-threatening allergic reaction to injected anesthetics, which develops as a rigid, uncompromising behavior. The differential diagnosis of a real allergy to local anesthetics, panic disorder, or needle phobia is extremely important. True allergy can cause life-threatening anaphylactic shock. In such patients, the use of local anesthetics should be strictly avoided. In the case of panic disorder, some data in the literature suggest that the immune reaction regulated by IgE can be increased, which means a possible higher risk of anaphylactic shock. Because of this, great care should be exercised if using local anesthetics with these patients. For needle-phobic patients, the contraindication for the use of local anesthetics (if any) is only psychological.

Psychosomatic Manifestations in Dentistry

Because of the multiple psychological couplings and importance of the mouth and teeth, many of the psychopathological mechanisms related to sexuality, aggressivity, autoaggressivity, or death anxiety can lead to orofacial manifestations, especially if these important psychological and symbolic functions are damaged by tooth or mouth disorders. Acute psychological stress conditions (e.g., existential trauma, workplace problems, relationship problems with the sexual partner) or chronic conditions (e.g., depression, neuroses, chronic anxiety, death anxiety, schizophrenic or paranoid reactions) may serve as a background. These manifestations more frequently appear in women, usually in the second half of life, although they can appear in children or in young adults as well. The most frequent symptoms are atypical facial pain, burning mouth syndrome, myofascial pain, temporomandibular dysfunction, bruxism and other parafunctions, gagging, psychogenic taste disorders, certain recurrent oral ulcerations or inflammations, some oral allergic reactions, psychogenic occlusal problems, tic, psychogenic salivation problems, and oral discomfort. The symptoms may appear singly or in combination. Such symptoms appear frequently in orthodontic and prosthodontic

treatments (psychogenic denture intolerance), since orthodontic treatments and dentures have a great impact on the aesthetic, sexual, nutritional, phonetic, and, consequently, symbolic function of the teeth. In addition, orthodontic and prosthodontic treatments can be rather uncomfortable, extremely expensive, and time-consuming, which can cause the patient to develop strong emotions toward the dentist (and/or assistant). These factors may induce pressure, aggression, and complication of the dentist–patient–assistant relationship.

Prevention and Treatment Possibilities

Prevention of stress-related problems can be based on introducing a framework of mental hygiene to the dental treatment, including skilled communication with the patient and monitoring of the patient–dentist–assistant interpersonal relationships. Great care should be taken to acquiesce to the wishes of the patient regarding his or her treatment, both conscious and unconscious. Conscious wishes (e.g., to achieve a nice smile, for treatment to be inexpensive and painless) are usually easily detectable. Understanding unconscious wishes (e.g., to look younger, to stop the appearance of aging, to be loved by the dentist) may be more challenging but is similarly important for preventing the manifestation of symptoms.

Several possibilities for treatment can be considered. In the case of dental fear, sedation is recommended. Short-acting benzodiazepines are the most frequently used drug, either intraorally as a pre-medication or intravenously for deep (conscious) sedation during treatment. A mixture of nitrous oxide and oxygen is also frequently used for sedation during treatment; it is often advantageously combined with several hypnosis techniques. Hypnosis or relaxation techniques as single therapies can be effective as well.

In the case of psychosomatic manifestations, the patient usually regards his or her symptoms as a somatic or technical problem and asks for a repetition or correction of previous dental treatment. An early diagnosis is crucial, because repeated somatic dental treatment worsens the prognosis, fortifies the patient's false conception, and may lead to further loss of oral tissue. Special techniques should be used to lead the patient to accept psychotherapy or psychiatric treatment. For this purpose, psychotherapy-oriented discussions should be gradually introduced during placebo and/or palliative dental treatment (alleviating or relieving symptoms without surgery). Relaxation, biofeedback, and hypnotic techniques can be useful as well, most advantageously

as a combination with a form of physiotherapy (e.g., magnetotherapy, transcutaneous electrical nerve stimulation (TENS), photoacoustic stimulation, massage). For older patients, a religious-based treatment (e.g., pastoral therapy, pastoral counseling) may also be needed as an effective means of treating death anxiety-related manifestations.

In many cases, a dentist skilled in the above methods can effect a notable improvement in the patient's symptoms or even complete recovery. In other instances, a referral to a psychotherapist or psychiatrist may be necessary.

Definition and Characteristics

Etiology

Assessment with the SCID-D-R

Case Study

Conclusions

Glossary

<i>Amnesia</i>	A specific and significant block of past time that cannot be accounted for by memory.
<i>Depersonalization</i>	Detachment from one's self, e.g., a sense of looking at one's self as if one were an outsider.
<i>Derealization</i>	A feeling that one's surroundings are strange or unreal. Often involves previously familiar people.
<i>Dissociation</i>	Disruption in the usually integrated functions of conscious memory, identity, or perception of the environment. The disturbance may be sudden or gradual, transient or chronic.
<i>Identity alteration</i>	Objective behavior indicating the assumption of different identities, much more distinct than different roles.
<i>Identity confusion</i>	Subjective feelings of uncertainty, puzzlement, or conflict about one's identity.

Depersonalization is characterized by a sense of detachment from the self. The symptom itself may manifest in a variety of axis I or axis II psychiatric disorders. The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) prefers to define depersonalization not in functional or nosologic terms, but phenomenologically, as in an alteration

in the perception or experience of the self. The sense of detachment itself may be experienced in various ways. Commonly it appears as out-of-body experiences giving a sense of division into a participating and an observing self, resulting in the sense of going through life as though one were a machine or robot. In some cases, there exists a feeling that one's limbs are changing in size or are separated from the body.

It is important to distinguish between recurrent severe depersonalization that is characteristic of the dissociative disorders, including depersonalization disorder, and mild or moderate episodic depersonalization sometimes observed in patients with other nondissociative axis I or II disorders, and the isolated episode experienced by persons in the healthy population (normal controls).

Definition and Characteristics

Although depersonalization was first described in 1872, it was not named until 1898, when Dugas contrasted the feeling of loss of the ego with a real loss. In 1954, Ackner remedied the lack of clear-defined boundaries of the symptom by describing the four salient features: (1) feeling of unreality or strangeness regarding the self, (2) retention of insight and lack of delusional elaboration, (3) affective disturbance resulting in loss of all affective response except discomfort over the depersonalization, and (4) an unpleasant quality that varies in intensity inversely with the patient's familiarity with the symptom. Steinberg defined depersonalization as one of five core symptoms of dissociation (see above), the other four consisting of amnesia, derealization, identity confusion, and identity alteration. Each of the five dissociative disorders has characteristic symptom profiles of these core dissociative symptoms. For this reason, it is essential that the symptom of depersonalization is evaluated within the context of the other dissociative symptoms and not as an isolated symptom.

Episodes of depersonalization accompany or even may precipitate panic attacks and/or agoraphobia; they may also be associated with dysphoria. Chronic depersonalization frequently results in the patient's acceptance of the symptoms, in a manner of resignation. Patients experience difficulty putting their experience into words, but often compare their feelings to such states as being high on drugs, seeing themselves from the outside, or floating in space and watching themselves. Other descriptions of depersonalization include feelings of being unreal, or in severe cases, include the feeling of being numb or dead, or the lack of all feeling, which may be attributed to and/or misdiagnosed as depression.

Depersonalization has been reported to be the third most common complaint among psychiatric patients, after depression and anxiety. Incidence of actual depersonalization has been difficult to determine because of (1) the relative strangeness of the symptoms, (2) the difficulty patients experience in communicating them, and (3) the lack, until recently, of diagnostic tools for the systematic assessment of depersonalization. Detection is further complicated by the fact that depersonalization is not accompanied by altered external or social behavior, but by an altered state of perception on the part of the patient.

Etiology

Various biological and psychodynamic theories have been advanced for the etiology of depersonalization: (1) physiological or anatomical disturbance, with feelings of depersonalization produced by temporal

lobe function and various metabolic and toxic states, (2) the result of a preformed functional response of the brain to overwhelming traumata, (3) a defense against painful and conflictual affects such as guilt, phobic anxiety, anger, rage, paranoia, primitive fusion fantasies, and exhibitionism, (4) a split between the observing and the participating self, allowing the patient to become a detached observer of the self, and (5) the result of a child's being raised in an environment that systematically fails to know some part of the child, who then experiences that part as tentative and as a result is unable to accurately assess the self.

Depersonalization has been reported to be a normal reaction to life-threatening events, such as accidents, serious illnesses, near-death experiences, anaphylactic reactions, and complications of surgery. Depersonalization is frequent among victims of sexual abuse, political imprisonment, torture, and cult indoctrination. Symptoms of depersonalization are often associated with hypnosis, hypnogogic and hypnopompic states, sleep deprivation, sensory deprivation, hyperventilation, and drug or alcohol abuse.

The development of specialized tests for the assessment of dissociation has led to an increase in investigations furthering our understanding of depersonalization. Depersonalization, as a brief, isolated symptom, is nonspecific and not necessarily pathognomonic of any clinical disorder. Research indicates that it is the persistence and nature of depersonalization that differentiates depersonalization in normal subjects versus persons with dissociative and nondissociative disorders. [Table 1](#) is useful for distinguishing between normal and pathological

Table 1 Distinguishing between normal and pathological depersonalization

<i>Common mild depersonalization</i>	<i>Transient depersonalization</i>	<i>Pathological depersonalization</i>
Context		
Occurs as an isolated symptom	Occurs as an isolated symptom	Occurs within a constellation of other dissociative or nondissociative symptoms or with ongoing interactive dialogue
Frequency		
One or few episodes	One or few episodes that are transient	Persistent or recurrent depersonalization
Duration		
Depersonalization episode is brief; lasts seconds to minutes	Depersonalization of limited duration (minutes to weeks)	Chronic and habitual depersonalization lasting up to months or years
Precipitating factors		
• Extreme fatigue • Sensory deprivation • Hypnogogic and hypnopompic states • Drug or alcohol intoxication • Sleep deprivation • Medical illness / toxic states • Severe psychosocial stress	• Life-threatening danger. This is a syndrome noted to occur in 33% of individuals immediately following exposure to life-threatening danger, such as near-death experiences and auto accidents (Noyes et al., 1977) • Single, severe psychological trauma	• Not associated with precipitating factors in column 1. • May be precipitated by a traumatic memory. • May be precipitated by a stressful event, but occurs even when there is no identifiable stress. • Occurs in the absence of a single immediate severe psychosocial trauma.

Table 2 The spectrum of depersonalization on the SCID-D-R

<i>DID and DDNOS</i>	<i>Non-dissociative and personality disorders</i>	<i>No psychiatric disorder</i>
Depersonalization questions elicit descriptions of identity confusion and alteration	No spontaneous elaboration	No spontaneous elaboration
Includes interactive dialogues between individual and depersonalized self	No interactive dialogues	No interactive dialogues
Recurrent–persistent	None–few episodes	None–few episodes

Note: DID = Dissociative Identity Disorder, DDNOS = Dissociative Disorder, Not Otherwise Specified.

depersonalization. [Table 2](#) summarizes the spectrum of depersonalization.

The differential diagnosis tree of depersonalization ([Figure 1](#)) illustrates procedures for distinguishing between depersonalization disorder and other disorders that may resemble it. The differential diagnosis of patients experiencing recurrent or persistent depersonalization should include the dissociative disorders, various other psychiatric disorders, and possible medical disorders/organic etiology, most commonly acute head trauma, seizure disorders, and migraines.

Assessment with the SCID-D-R

The Structured Clinical Interview for DSM-IV Dissociative Disorders – Revised (SCID-D-R) is a diagnostic

tool for the comprehensive assessment of dissociative symptoms and disorders, including the systematic identification of depersonalization. Developed in 1985 and extensively field tested, it is the only diagnostic instrument enabling a clinician to detect and assess the presence and severity of five core dissociative symptoms and the dissociative disorders (dissociative amnesia, dissociative fugue, depersonalization disorder, dissociative identity disorder, and dissociative disorder not otherwise identified) as defined by DSM-IV criteria. The SCID-D-R is a semistructured diagnostic interview with good-to-excellent interrater and test-retest reliability and discriminant validity. Guidelines for the administration, scoring, and interpretation of the SCID-D-R are reviewed in the *Interviewer's Guide to the SCID-D-R*. Severity rating definitions were developed to allow clinicians

to rate the severity of symptoms in a systematic manner and are included in the guide.

The SCID-D-R can be used for symptom documentation and for psychological and forensic reports. Early detection of dissociative disorders, including depersonalization disorder, can be realized from the use of this specialized instrument, the format of which includes open-ended questions designed to elicit spontaneous descriptions of endorsed dissociative symptoms. The SCID-D-R has been demonstrated to be a valuable tool in differential diagnosis with patients of different ages (it can be used in adolescents as well as adults), backgrounds, previous psychiatric histories, and presenting complaints. It also plays a useful role in treatment planning, patient follow-up, and symptom monitoring.

Correct diagnosis is vital to proper treatment of the disorder. If the depersonalization is secondary to an underlying primary disorder, the symptom may be alleviated by treatment of the underlying illness. In instances in which patients experience only occasional episodes of depersonalization in the context of other nondissociative symptoms, the clinician may consider a diagnosis of nondissociative psychiatric disorder. The presence of depersonalization disorder itself will be characterized by recurrent depersonalization.

Case Study

The process of differential diagnosis of depersonalization may best be illustrated by presenting a case study. The study demonstrates the utility of the SCID-D-R in diagnostic assessment, patient education, and treatment planning. For space reasons, conventional formatting and content have been abbreviated.

Sample SCID-D-R Psychological Evaluation

Demographic information and chief complaint: Susan Walker is a 31-year-old administrative assistant at a community college who presented with the complaint of feeling detached from herself since adolescence.

Past psychiatric history: Although the patient had no history of hospitalization for psychiatric disturbance, she began treatment for an episode of depression that interfered with her employment and social relationships. Although admitting to past casual use of marijuana, she had never been in treatment for substance abuse disorder.

Family history: Susan had a younger sibling; both children grew up in an intact but emotionally unsupportive family. Patient reported that both parents suffered mood swings and unpredictable temper outbursts.

Mental status exam: Susan answered questions with relevant replies; although she seemed slightly depressed, her affect appeared full range. She denied hallucinations, both auditory and visual, and evidenced no psychotic thinking. She denied acute suicidal or homicidal ideas.

SCID-D-R evaluation: The SCID-D-R was administered to systematically evaluate the patient's dissociative symptoms and was scored according to prescribed guidelines. Significant findings from the SCID-D-R interview follow. Susan denied experiencing severe episodes of amnesia, but endorsed a persistent sense of depersonalization, resulting in distress and interference with occupational and personal functioning. This feeling of depersonalization had been chronic and occurred all the time rather than episodically. Although the feeling varied in intensity with her overall stress level, the experience of depersonalization was always characterized by a general sense of detachment from life, rather than by disturbances in body image or a split between participating and observing parts of the self. Only a single isolated out-of-body experience had occurred. Susan experienced feelings of derealization that varied in intensity with the depersonalization, but she reported the depersonalization as the most distressing symptom. She described recurrent anxiety and panic episodes triggered by the depersonalization; it was the combination of depersonalization and panic attacks that led to the depression that brought her into therapy. Susan reported that the depersonalization has eroded her sense of control over her occupational functioning and other significant areas of her life, but she did not attribute feelings of loss of control to identity confusion or alteration. She denied having internal dialogues, feelings of possession, or acquiring unexplained possessions or skills. Her descriptions of internal struggle were focused on her feelings of unreality, not on conflicts between different aspects of her personality or different personalities within herself.

Assessment: Susan's symptoms are consistent with a primary diagnosis of a dissociative disorder based on DSM-IV criteria and ICD-10 criteria. Specifically, in the absence of substance abuse disorder or other organic etiology, her severe chronic feelings of unreality toward herself and the accompanying dysfunction (in the absence of other dissociative symptoms such as identity confusion and alteration) are consistent with a diagnosis of depersonalization disorder.

Recommendations: Although detailed discussion of treatment for depersonalization disorder is beyond the scope of this article, it would be standard practice to conduct a follow-up interview to review the findings of the SCID-D-R evaluation, to educate

the patient regarding her symptoms, and to begin the process of individual psychotherapy.

Conclusions

Recent advances in the development of reliable diagnostic tools allow for early detection and accurate differential diagnosis of depersonalization. Research based on the SCID-D-R indicates that depersonalization occurs in individuals without psychiatric illness who experience none to few brief episodes, as well as in individuals with dissociative disorders who experience recurrent to ongoing episodes. In addition to the frequency of the depersonalization, the nature, severity, and context also distinguish cases of dissociative disorder from other nondissociative disorders. Further research is necessary in the form of controlled double-blind studies comparing the efficacy of pharmacotherapeutic agents as well as psychotherapeutic techniques. As the SCID-D-R allows for the assessment of the severity of depersonalization based on operationalized criteria, pharmacotherapy trials can now be systematically performed and can evaluate baseline and postmedication severity levels of depersonalization. Given the frequency of misdiagnosis in patients suffering from depersonalization and other dissociative symptoms, earlier detection of dissociative disorders using the SCID-D-R can allow for rapid implementation of effective treatment.

Depression Treatment Trials in Coronary Heart Disease Patients

Conclusion

Glossary

<i>Autonomic nervous system</i>	The system that controls internal organs without a person being consciously aware. There are two parts to this system: the sympathetic nervous system and the parasympathetic (or vagal) nervous system.
<i>Cognitive-behavior therapy (CBT)</i>	A structured, usually time-limited, form of psychotherapy with active therapist involvement involving exercises and homework to alter dysfunctional thought patterns that are believed to underlie and perpetuate depression.
<i>Endothelial dysfunction</i> <i>Endothelium</i>	One of the earliest signs of the development of coronary heart disease. The lining of the arteries; responsible for arterial dilation and constriction in response to systemic demands and chemical stimuli.
<i>Heart-rate variability</i>	The degree to which the length of time between heart beats differs from beat to beat. Low heart-rate variability is a sign of inadequate vagal protection in the autonomic nervous system and predicts cardiac death in individuals with coronary heart disease.
<i>Parasympathetic nervous system</i>	Part of the autonomic nervous system that controls relaxation and promotes digestion; also called the vagal nervous system.
<i>Sympathetic nervous system</i>	Part of the autonomic nervous system that directs the fight-or-flight response to stress.

Sympathetic-vagal balance

The balance between the sympathetic nervous system and the parasympathetic (or vagal) nervous system; this balance is altered in depression.

Ventricular function

A measure of the heart's ability to pump blood; it is often reduced following myocardial infarction because of the damage that occurs to the heart muscle.

Introduction

Depression and coronary heart disease (CHD) are among the most prevalent disabling medical conditions worldwide. The Global Burden of Disease Study predicted that, by 2020, depression and CHD will be the two leading causes of early death and disability in the world. The term depression most frequently refers to a mental state with sustained sadness or loss of interest lasting at least several weeks, coupled with other symptoms such as fatigue, reduced sleep, and appetite and leading to significant occupational or interpersonal impairment. CHD includes all clinical manifestations associated with damage to the myocardium due to acute or chronic ischemia, which itself is most commonly caused by atherosclerotic narrowing of the coronary arteries. Interestingly, psychological stress, such as interpersonal conflicts, perceived or real losses, and work stress, are thought to contribute to the acute exacerbation of depression as well as of CHD.

Definitions of Depression

The *Diagnostic and Statistical Manual of Mental Disorders* (4th edn.; DSM-IV) of the American Psychiatric Association defines major depression as at least 2 weeks of daily (lasting most of the day) sadness or loss of interest plus at least five of the following symptoms: changes in appetite, changes in sleep patterns, psychomotor agitation or retardation, loss of energy or fatigue, feelings of worthlessness, inability to concentrate or make decisions, and thoughts of suicide or death.

Studies conducted in hospitalized cardiac patients have found that about one in six patients meet the criteria for a major depressive episode. This high peak prevalence during the hospitalization subsides, with approximately 10% of CHD patients depressed at 3 months after discharge. However, many patients do not meet the full criteria for major depression, but nevertheless present elevated levels of depressive

symptoms. These patients may have a variety of clinical diagnoses. Some may suffer from a major depression in partial remission or dysthymia (chronic low-level depression); others may suffer from an adjustment disorder. There are many different self-report scales available to measure the overall intensity of depressive symptoms. The Beck Depression Inventory (BDI) is the most commonly used in research with CHD patients.

Even if major depression is not present, however, having high levels of depressive symptoms increases a patient's risk of cardiovascular events. Although major depression and elevated depressive symptoms are approximately three times as common in CHD patients as in the general community, the prevalence of depression in CHD patients is similar to that in patients with other chronic medical conditions.

The Course and Consequences of Depression in Coronary Heart Disease Patients

As for depressed patients without medical illnesses, the course of depression in CHD patients is frequently chronic. More than half of those who experience major depression during hospitalization after a myocardial infarction (MI, or heart attack) remain depressed or have elevated symptoms of depression 1 year later.

However, as important as its chronicity is the fact that depression is associated with a worse cardiac prognosis. Several reviews and meta-analyses have concluded that both major depression and high levels of depressive symptoms predict cardiac mortality in patients with established CHD, as well as the incidence of CHD among previously healthy subjects. The impact of depression is independent of other prognostic variables; that is, it is not explained by other possible confounding factors. This means, for example, that depression predicts cardiac mortality even after statistical control for other predictors of mortality such as age, ventricular function, hypertension, and diabetes. In addition to its independent impact on prognosis, the size of the impact of depression on CHD events is as large as that of these other important prognostic factors. Depression at least doubles the risk of cardiac mortality over time, and the risk increases with the severity of depressive symptoms.

INTERHEART, a very large case-control study conducted in 52 countries across all continents compared levels of modifiable risk factors in more than 11,000 survivors of a first MI and more than 13,000 control subjects. The study found that the population attributable risk (PAR) for depression is 9%, a risk as large as that of diabetes. The PAR takes into account the prevalence and degree of risk associated with a

particular risk factor and is interpreted to mean that, if depression could be eliminated at the population level, we would observe a worldwide reduction of 9% in the incidence of first MIs.

The INTERHEART study also evaluated the contribution of different dimensions of stress to the incidence of MI. It found that all four dimensions of stress measured in the study (stress at work, stress at home, financial stress, and general stress) predicted the incidence of MI, with the PARs for stress ranging between 8 and 12%. In addition, the study found that a measure of locus of control, evaluating how much a person feels that he or she can control life circumstances, also predicted the incidence of MI, with a PAR of 16%. Finally, the occurrence of stressful life events in the last year, such as the death of a spouse or other family member, marital separation or divorce, or major familial conflict, was also more frequent among first MI patients than controls. In summary, this landmark study found that, on a worldwide basis, the contribution of psychosocial stress and depression to the incidence of MI was just behind that of smoking and was greater than that of abdominal obesity. INTERHEART also confirmed that the impact of depression and other psychosocial stresses is independent of age, smoking status, and other cardiovascular risk factors. It underscores the importance of the emotional and behavioral factors in physical health, and it should stimulate research to reduce depression, stress, and their consequences.

Mechanisms

Many biological pathways may be involved in the link between depression and CHD. Depression is similar to a state of chronic, severe psychological stress, and many of the biological systems involved in the stress response are dysregulated in depressed patients regardless of whether or not they have CHD. The sympathetic-vagal balance is tipped toward more noradrenergic activity, heart-rate variability is reduced, and there is an increased risk of ventricular arrhythmias. There is also an augmentation of the innate inflammatory response with more pro-inflammatory cytokines. Platelet activation is increased, facilitating blood-clot formation. There is hyperactivity of the hypothalamic-pituitary-adrenal (HPA) axis, which influences lipid and carbohydrate metabolism. In addition, it has been recently shown that depressed young adult patients without CHD have endothelial dysfunction, one of the early markers of atherosclerotic burden.

Because of the obvious role of the selective serotonin reuptake inhibitor (SSRI) antidepressants in mood regulation, there has been a great deal of interest in their potential cardiovascular benefits. Platelets contain serotonin granules that are secreted during the

platelet activation phase, a process that facilitates blood-clot formation through the activation of the platelet's own serotonin receptors. In addition, platelets have a specific serotonin transporter, which acts to move (reuptake) the secreted serotonin back inside the platelet. SSRIs block this transporter, therefore gradually depleting serotonin in the platelets. Consequently, after several weeks of treatment, SSRIs seem to have blood-thinning effects. However, it is unknown whether this effect is of enough clinical relevance to prevent thrombotic cardiovascular events.

It is also possible that some environmental or genetic factors contribute to the physiopathology of CHD and depression at the same time. For example, a lower dietary intake of long-chain omega-3 fatty acids has been shown to predict the incidence of CHD and a wide variety of mood disorders. There is hope to identify common genetic predispositions for mood disorders and CHD. Specifically, the genes involved in the regulation of the biological systems mentioned thus far (i.e., the sympathetic-parasympathetic system, the inflammatory response, the HPA axis, platelet activation, and thrombus formation) can be profiled and used to evaluate whether specific genetic variations predict the development of CHD, depression, or both. For example, the genes regulating serotonin synthesis, metabolism, and reuptake, such as the serotonin transporter-linked polymorphic region (5-HTTLPR), may be associated with an increased risk of depression because of its role in the brain and with an increased risk of cardiovascular events because of its role in platelet aggregation.

Depression Treatment Trials in Coronary Heart Disease Patients

With the current deluge of mega-trials in cardiology testing new drugs and devices to prevent cardiovascular events among CHD patients, it is very disappointing that only one trial was specifically designed to evaluate whether an intervention for depression has an impact on CHD events. This is, at least partially, because of lack of funding resources; a depression treatment-CHD trial would necessarily depend on peer-reviewed public funding, whereas most of the large phase III drug trials in cardiology are currently supported by the pharmaceutical industry.

ENRICH (Enhancing Recovery in Coronary Heart Disease) is the only trial carried out to date to evaluate the impact of depression treatment on cardiac events. ENRICH was a National Heart, Lung, and Blood Institute (NHLBI)-sponsored, multicenter trial that assessed the potential benefit of 6 months of CBT in some 2400 depressed post-MI patients. Although patients receiving CBT experienced a significantly greater improvement in depression than

those in the usual-care group, this study was unable to demonstrate that CBT prevented the recurrence of cardiac events. The physicians of patients in the usual-care group were informed that their patients were depressed, and there was a high rate of prescription of antidepressant medications in the usual-care group, reducing the contrast between the groups. Other earlier controlled clinical trials designed to treat psychological distress, rather than depression *per se*, were also not successful in demonstrating that treating distress reduces cardiac events.

Conclusion

Despite the extensive epidemiological data showing that an increased risk of cardiac events is associated with depression and considerable animal and human research suggesting that various physiopathological changes, similar to those observed in chronic severe stress, accompany depression, the data from controlled clinical trials do not support the use of any specific interventions for depression or psychological distress to prevent cardiac events in CHD patients.

Glossary

<i>Affect</i>	The objective (observable) component of emotions (appearing depressed, angry, elated, etc.), in contrast to mood.
<i>Anti-depressants</i>	Drugs that are used in the treatment of depression.
<i>Bipolar illness (disorder)</i>	Manic-depressive illness (disorder).

Cerebral cortex The outer layer of the brain, composed mainly of nerve cells (neurons).

Cerebral ventricles Cerebrospinal fluid-filled spaces within the brain.

Electroconvulsive therapy (ECT) A treatment for severe depression or bipolar disorder; a brief electric current is passed through the brain to induce a grand mal convulsive seizure.

Mood The prevailing subjective (experienced) emotional tone (sadness, happiness, elation, anger, etc.), in contrast to affect. (Mood is to affect as climate is to weather.)

Neurotransmitters Chemicals that carry messages from one nerve cell to another.

Introduction

The term depression covers a spectrum of disorders. These range from temporarily feeling down about something that has gone wrong in one's life to long and severe depressions that have a genetic and biological basis and that often are incapacitating to the afflicted person in his or her occupational and social life. The term manic-depression likewise covers a spectrum of disorders from temperamental instability of mood (i.e., cyclothymia) to a severe psychotic disorder with recurrent episodes of mania and depression. These are inappropriate swings of mood and behavior in opposite directions – excessive elation as well as significant depression.

Depression and manic-depression are psychiatric disorders that currently are considered functional, in that there is no clearly understood central nervous

system (CNS) pathophysiology underlying them. This is a nomenclature in transition, however – as knowledge about the pathology of the brain in these and other psychiatric illnesses increases, the adjective “functional” conveys less and less meaning. Furthermore, when these mood disorders are so severe that they impair the daily life of the individual, somatic (physical) treatments are almost always required, including antidepressants, mood-stabilizing drugs such as lithium, and, when drug therapy fails, electroconvulsive therapy (ECT).

This article focuses on the more severe disorders of mood, in particular major depression (also called unipolar depression) and bipolar disorder. The CNS substrates of these illnesses are being examined in several ways, and their genetic underpinnings are slowly being defined. Structural and functional imaging studies of the brain are providing some anatomical localization, limited by the resolution of the imaging techniques and the particular imaging method used.

Several classes of antidepressant drugs are useful for treating major depression, but the interactions among chemical systems (neurotransmitters) in the brain make it difficult to predict which antidepressant will work best for a particular patient. Lithium is the most broadly effective treatment for bipolar illness, but a number of anticonvulsant and antipsychotic drugs, as well as antidepressants, also may be helpful in various clinical circumstances. Stress can play a major role in the severity and duration of both major depression and bipolar disorder. Moreover, the illnesses themselves, given the incapacitating nature of their symptoms, can be very stressful to afflicted people. In both disorders, one's psychological pain and despair can be so severe that suicide may be contemplated and even attempted.

Clinical Characteristics of Major Depression and Manic-Depression

Major depression and manic-depression are classified among the mood disorders. Major depression (unipolar depression) consists of one or more depressive episodes, defined as 2 weeks or more of depressed mood or loss of interest or pleasure in nearly all activities, with at least four additional symptoms from the following: increased or decreased appetite and/or weight; increased or decreased sleep; change in psychomotor activity (retardation or agitation); decreased energy; feelings of worthlessness or guilt; difficulty thinking, concentrating, or making decisions; and repeated thoughts of death, including suicidal thoughts, plans, or attempts. The symptoms must be severe enough to cause significant distress or to interfere with the person's occupational or social

functioning. Finally, the major depressive episode must not be a direct result of a drug or an underlying medical condition.

Based on these criteria for the diagnosis of major depression, we can see that it is a very broad category of mental illness. The diagnostic criteria are disjunctive in that there are few mandatory symptoms, and individual patients may have few symptoms in common. To address this concern about heterogeneity, subtypes of major depressive disorder have been defined that require a more restricted list of symptoms. In particular, melancholic major depression focuses on physiological symptoms. Its diagnosis requires having the criteria for major depression plus either loss of pleasure in all (or almost all) activities or lack or reactivity to usually pleasurable stimuli, along with at least three additional symptoms from the following: a distinct quality to the depressed mood (different from a feeling of grief), the depressive symptoms being regularly worse in the morning, early morning awakening (at least 2 hours earlier than usual), marked psychomotor retardation or agitation, significant loss of appetite and/or weight, and excessive or inappropriate guilt. These also are disjunctive criteria, associated with significant heterogeneity. Melancholic major depression usually requires antidepressant medication, and sometimes ECT, for effective treatment.

Another feature of major depression may be the presence of psychotic features (delusions that are usually mood-congruent, or hallucinations). This form of depression may require treatment with antipsychotic as well as antidepressant drugs. The timing of major depressive episodes also may be linked to the season of the year, particularly to the light-dark cycle – seasonal affective disorder, as this condition is known, usually occurs in the winter when the days are short. Exposure to very bright light for several hours each morning may be useful as an adjunct to antidepressant drugs in the treatment of seasonal affective disorder.

A manic episode consists of a period of abnormally and persistently elevated, expansive, or irritable mood lasting for at least 1 week (less if the person is hospitalized), with at least three of the following additional symptoms: inflated self-esteem or grandiosity, decreased need for sleep, pressure of speech, flight of ideas or subjective feeling that his or her thoughts are racing, being easily distracted, increased activities (work, social, sexual) or psychomotor agitation, and excessive involvement in pleasurable activities that are potentially harmful (e.g., excessive alcohol intake, buying sprees, sexual indiscretions, or foolish business decisions).

Although these diagnostic criteria also are disjunctive, the heterogeneity of manic patients is generally much less than that of depressed patients. As with

major depression, the symptoms must be severe enough to cause significant distress or to interfere with the person's occupational or social functioning, and the manic episode must not be a direct result of a drug or an underlying medical condition. And, as with major depression, psychotic features also may be part of the clinical picture. Finally, although mania and depression are conceptualized as polar opposite forms of mood disorder (hence the term bipolar disorder), coexisting manic and depressive symptoms are very common. When depressive and/or anxiety symptoms are prominent in a manic episode, the term mixed bipolar disorder is applied. Analyses of symptoms in mania have consistently revealed dimensions of depression and anxiety, elation-grandiosity, pressured behavior, psychosis, and irritable hostility. These separate components may display differential responsiveness to treatments; for example, elation-grandiosity may respond to lithium, irritable hostility to anticonvulsant mood stabilizers, and psychosis to antipsychotic drugs.

Bipolar I disorder is defined as a clinical course of one or more manic or mixed episodes, the latter being defined as criteria for both manic episode and major depression when they have been met nearly every day for at least 1 week. The most common form of bipolar illness is manic episodes alternating with major depressive episodes, which may or may not be separated by intervals of normal mood. Mixed episodes are less common, and the rarest pattern is to have manic episodes only, with no depressive features. Occasionally, several major depressive episodes may occur before the first manic episode becomes evident. Bipolar II disorder is defined as recurrent major depressive episodes with hypomanic episodes. Hypomanic episodes must meet the criteria for manic episodes, except they can be of shorter duration and lesser severity.

Epidemiologic studies indicate that the lifetime prevalence of major depression is about 10–25% for women and about half that for men; thus, it is one of the commonest psychiatric disorders. Fewer than half these survey-defined cases come to clinical attention, however. About twice as many adolescent and adult females are affected as males. In children, the prevalence of major depression is about equal between boys and girls. Thus, the hormonal changes of puberty may play a role in its greater incidence in adolescent and adult females. In contrast to widespread clinical belief a few decades ago, there is no increase in major depression in women at the time of menopause.

Approximately one-third of clinical major depressions improve with treatment and do not recur; approximately one-third show remission with treatment but do recur a number of times throughout the life

of the individual; and approximately one-third may improve with treatment, but there remains a chronic, underlying depression of lesser severity. This chronic depression may meet the criteria for dysthymic disorder, which requires, among other criteria, depressed mood for more days than not, for at least 2 years. Major depressive episodes occurring against a background of dysthymia has been called double depression. The term refractory depression is applied to patients who fail to respond to at least two adequate trials of treatment; these make up approximately 15% of clinical major depressive episodes.

Major depression can co-occur with many other psychiatric illnesses such as anxiety disorders, eating disorders, drug abuse and alcoholism, dementias, and psychotic disorders, as well as in the context of many medical illnesses. In these instances, it is referred to as secondary major depression, in contrast to primary major depression, in which the depressive illness itself predominates. Primary major depression also may have some of these illnesses as secondary diagnoses; the determining factor is which came first. For example, anxiety symptoms sufficient to meet a diagnosis of generalized anxiety disorder occur with some frequency in major depression and are considered secondary because the depressive illness preceded them. Regardless of whether the depression is primary or secondary, these comorbid conditions have significant adverse effects on the clinical course of patients with major depression.

Although the classical descriptions of major depression and mania do not focus on cognitive function, it is now clear that pervasive, subtle impairments of executive function and declarative memory do occur during episodes of mood disturbance and that these features sometimes persist between episodes, especially in bipolar subjects. In elderly patients, more striking cognitive impairment may occur as part of a depressive episode. In particular, depressive pseudodementia (false dementia) should be considered in elderly depressed patients who have significant impairment of cognitive function and who might otherwise be diagnosed as having a dementia such as Alzheimer's disease. The distinction between depressive pseudo-dementia and true dementia is extremely important, because pseudo-dementia resolves with successful treatment of the underlying depression, whereas true dementia generally does not respond to currently available treatments.

Not only is major depression an important illness today, but within 15 years it is predicted to become the second most incapacitating illness throughout the world, just a small percentage behind cardiovascular disease. Thus, major depression is fast becoming a significant public health problem. As global

populations age, a newly recognized form of major depression in the elderly, termed vascular depression, is increasing in prevalence. This condition results from disease of the small arteries supplying the brain. It has an unusually late age of onset for unipolar depression (after age 50), and it is recognized by the magnetic resonance imaging (MRI) features of deep white-matter hyperintensities; subcortical gray matter hyperintensities, especially in the caudate nuclei; and micro-infarcts (tissue death from blocked blood supply). All these features occur as well in vascular dementia, which is a significant long-term outcome of vascular depression. Risk factors for vascular depression include hypertension, diabetes mellitus, and abnormal plasma lipid profiles.

The lifetime prevalence for bipolar I illness is about 1% and for bipolar II illness about 0.5%. These illnesses usually begin in adolescence or young adulthood and are equally prevalent in males and females. As mentioned, recurrent alternating manic and depressive episodes represent the most common form; if four or more manic or depressive episodes occur within a year, the illness is considered rapidly cycling and may require frequent hospitalizations and certain medication combinations for its control.

As with the other severe psychiatric disorders, both major depression and manic-depression can be made worse by stressful life situations. Major depression not uncommonly is preceded, if not precipitated, by a significant loss in a person's life, be it death of a significant other, job loss, or financial reversal. As mentioned, the psychological pain and turmoil of a severe depression, coupled with additional physical factors such as insomnia, can in turn be extremely stressful to the sufferer, and, on occasion, suicide may be considered the only way out. Fortunately, almost every major depression is treatable, and suicidal thoughts that are present in the depths of the depressive episode almost always disappear with treatment.

Bipolar disorder is more internally driven (less affected by external stressors), but the illness itself can have extremely stressful consequences for the individual. It is a challenging condition for family members as well, as evidenced by the fact that the rate of marital failure in bipolar disorder exceeds that in any other psychiatric condition. During a manic episode the person may run afoul of the law and be arrested; may spend his or her life savings foolishly and be reduced to poverty; or may behave recklessly and suffer physical injury, for example by reckless or drunken driving with involvement in an auto accident or sexual promiscuity with the contraction of a disease such as AIDS. Bipolar disorder, being a recurrent disorder, can result in many psychiatric hospitalizations over an individual's lifetime.

Biological Characteristics of Depression and Manic-Depression

There appears to be a genetic contribution to both major depression and bipolar disorder. Both illnesses more frequently coexist in monozygotic (single-egg) than in dizygotic twins, but the difference is much more pronounced for bipolar disorder. Similarly, there is a higher incidence of these disorders in the first-degree relatives of patients with both major depression and bipolar disorder; again, the relationship is stronger for bipolar disorder. A consistent observation is that the most common psychiatric disorder in the relatives of subjects with bipolar disorder is unipolar depression. This has led to suggestions of a two-gene vulnerability in bipolar cases. For both of these illnesses, however, as for all the major psychiatric disorders, the modes of inheritance have not been established. Except for a few bipolar disorder families, the modes of inheritance do not appear to fit either an autosomal or an X-linked pattern but most likely are multifactorial, involving several genes of varying influence. Nongenetic contributing factors, as well as different genetic loadings in different families, may interact to produce the same phenotypic outcome.

A particularly intriguing area of research is the interaction of gene polymorphisms and life stresses in the onset of major depressive episodes. A particular polymorphism in the serotonin transporter gene, the presence of two short alleles, appears to confer a greater vulnerability to depressive episodes following mild stressful life events than the presence of either one or two long alleles. There is only a weak overall relationship between the serotonin transporter polymorphism and occurrence of major depression, so life stresses apparently are the precipitating factors. The genetic polymorphism confers vulnerability to developing depression following less severe stresses.

There are several neurochemical theories of the etiology of depression and bipolar disorder, all of which involve abnormal function of CNS neurotransmitters and/or the chemical changes they activate in nerve cells (neurons). Neurotransmitters (for example serotonin, norepinephrine, and dopamine) are chemicals in the brain that are released by neurons and carry a chemical message across a short space (synapse) to neighboring neurons that have receptors for that neurotransmitter. Deficiencies of norepinephrine and serotonin neurotransmission and excessive acetylcholine neurotransmission are among the oldest theories of depression and best supported by research studies.

In both unipolar major depression and the depressive phase of bipolar disorder, reductions in the metabolic products of norepinephrine and serotonin have

been found in blood, urine, and cerebrospinal fluid, suggesting that both these neurotransmitter systems may be underactive, but the reductions in metabolites have been relatively small. In manic patients, the administration of physostigmine, a drug that inhibits the breakdown of acetylcholine, immediately stops the mania and produces a depressionlike state. Physostigmine also produces a depressionlike state in normal subjects. These findings suggest an overactivity of cholinergic neurotransmission in depression, and other studies have shown depressed patients to be supersensitive to cholinergic drugs in their sleep patterns, constriction of the pupils of their eyes, and so forth.

The most compelling evidence for the neurotransmitter theories of depression comes from the effects of drugs used to treat major depression and bipolar disorder. There are several classes of antidepressant drugs, and many of them block the cell membrane transporters for norepinephrine and/or serotonin, which recycle the neurotransmitters from the synapse back into the nerve cells that released them. By blocking transporter uptake, antidepressants increase synaptic neurotransmitter concentrations. Studies have shown that, in the intact human being, even very specific neurotransmitter uptake inhibitors eventually influence multiple neurotransmitter systems because of the physiological interactions among them. If one neurotransmitter system is perturbed by a drug acting on it specifically, the other systems tend to change to come back into balance with it.

More recent theories of antidepressant drug action emphasize follow-on actions of the drugs beyond inhibiting neurotransmitter reuptake by monoaminergic neurons. For example, an intracellular cascade occurs involving the activation of intracellular messengers (adenylyl cyclase and tyrosine protein kinases, the transcription factor cAMP response element binding protein (CREB), and increased mRNA for neurotrophins such as brain-derived neurotrophic factor (BDNF)).

The time course for full clinical response to all antidepressant drugs is 3–6 weeks, even though their specific pharmacological effects occur within 12–24 h. What is common to almost all antidepressants is that downregulation of postsynaptic noradrenergic receptors in the CNS occurs over the same number of weeks as required for the clinical response. Noradrenergic receptor downregulation may be an ultimate result of the increased availability of norepinephrine as a synaptic neurotransmitter, signaling that noradrenergic neurotransmission has increased to such an extent that the number and sensitivity of postsynaptic receptors need to be reduced in compensation. This finding suggests that a common neurochemical

pathology in depressed patients may be a relative underactivity of noradrenergic neurotransmission, which is rectified by drug treatment. The restoration of noradrenergic transmission by antidepressant treatments, including ECT, may be linked to the trophic action of BDNF in restoring functional synapses between noradrenergic neurons and their target neurons in prefrontal cortex and limbic system sites.

There are disturbances in several physiological systems that occur as part of depression and the depressive phase of bipolar disorder. Sleep disturbance has been mentioned as part of the diagnostic criteria. Electrophysiological studies of sleep (polysomnography) have revealed typical changes, including less total sleep time, fragmentation of the orderly cycling of sleep stages with more frequent awakenings throughout the night, and early occurrence of rapid eye movement sleep (REM or dreaming sleep). In normal people, the first REM episode occurs about 60–90 min after sleep is established (REM latency). This interval may be severely shortened in major depression, so much so that the person may go directly into REM sleep when sleep is first established (sleep-onset REM). The occurrence of REM sleep is influenced by CNS cholinergic neurotransmission; as mentioned, the administration of cholinergic neurotransmission-stimulating drugs to depressed people and control subjects while asleep produces a significantly shorter REM latency in the depressives than in the controls. This is one of the findings supporting the cholinergic overdrive hypothesis of major depression.

Another important physiological disturbance in major depression and bipolar disorder is increased activity of the hypothalamic-pituitary-adrenal cortical (HPA) axis. This endocrine axis consists of cells in the hypothalamus of the brain that secrete corticotropin-releasing hormone (CRH) and vasopressin (AVP), which are carried to the anterior pituitary gland and stimulate the secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary into the blood stream. In turn, ACTH stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids, and adrenal androgens into the bloodstream. Glucocorticoid hormones increase glucose production in the liver and promote lipid breakdown in fat tissue, thereby increasing circulating glucose available for muscle and other tissue use. The principal glucocorticoid in humans is cortisol (hydrocortisone). Mineralocorticoid hormones reduce the excretion of sodium and enhance the excretion of potassium and hydrogen ions by the kidney; the principal mineralocorticoid in humans is aldosterone. Adrenal androgenic hormones have weak male sex hormonelike effects.

The HPA axis is very responsive to both physical and psychological stressors. The secretion of CRH is

regulated by several of the CNS neurotransmitters considered important in depressive illness, including norepinephrine, serotonin, and acetylcholine. The increased activity of this endocrine axis that occurs in 30–50% of patients with major depression and in the depressive phase of bipolar disorder is likely caused by an underlying neurotransmitter dysfunction in the brain. Increased HPA axis activity can be documented by the finding of increased ACTH and cortisol in blood, urine, and cerebrospinal fluid and by ACTH and cortisol resistance to suppression with the potent, synthetic adrenal glucocorticoid, dexamethasone. Dexamethasone acts primarily at the pituitary gland to suppress the secretion of ACTH, which, in turn, suppresses the secretion of hormones from the adrenal cortex. Resistance to dexamethasone suppression in depressed patients originally was interpreted as evidence of overdrive from the brain on the pituitary. However, it is now known that dexamethasone may be cleared from the body more rapidly in the nonsuppressing subjects, with resulting lower plasma dexamethasone concentrations. This factor has to be considered when the test is being used (see **Dexamethasone Suppression Test (DST)**).

When stimulated for a period of time, endocrine glands often hypertrophy (grow in size), and both increased pituitary size and increased adrenal gland size have been reported in major depression. Adrenal size reverted to control values following successful antidepressant treatment. These adrenal gland changes are similar to those occurring during and after chronic stress in animals. The long-term effects of chronic exposure to high cortisol levels in depressed patients include loss of bone density, impairment of immune function, increased incidence of adult-onset diabetes mellitus and cardiovascular disease, and premature mortality. Collectively, these are termed indicators of high allostatic load in depression.

Neuroimaging Studies in Depression and Manic-Depression

With the advent of neuroimaging techniques, it now is possible to probe the structure and function of the living human brain. Brain structure can be viewed with X-ray computed tomography (CT) and MRI. Magnetic resonance spectroscopy (MRS) can determine the concentrations of certain chemical substances in the CNS. Nuclear medicine techniques such as single-photon computed tomography (SPECT) and positron-emission computed tomography (PET) allow the visualization and quantitation of regional cerebral blood flow, glucose metabolic rate, and neurotransmitter receptor occupancy, which are indirect probes of regional neuronal function. SPECT and PET use

radiolabeled compounds as tracers; as these compounds decay, high-energy photons are emitted, which are counted by external detectors. The distribution of the tracer molecules is computed, and cross-sectional images of the brain are created in which image brightness is proportional to the underlying physiological process being measured. The newest technique, functional MRI (fMRI), also indicates blood flow in different areas of the brain.

Studies of brain structure with CT and MRI in patients with major depression and bipolar disorder have demonstrated a number of abnormalities, but it is not clear how specific these changes are. Enlarged cerebral ventricles in relation to overall brain size have been reported in a number of studies, but similar findings have been reported in patients with other psychiatric illnesses, such as schizophrenia. Different groups of patients (unipolar and bipolar), different ways of measuring and reporting ventricular volume, and different control groups have been used, but meta-analysis of many studies has pointed toward a significant enlargement of the ventricles in unipolar and bipolar patients compared to controls. The difference is more marked in elderly subjects. There appears to be no consistent relationship between structural changes in the brain and severity of the illness. Reduced volume of the subgenual anterior cingulate gyrus has been found in familial, pure, primary, unipolar depression, and this feature has been correlated with glial cell loss in the same region.

Reduced volume of the hippocampus also has been reported inconsistently in major depression. Initial suggestions that this feature is related to elevated cortisol exposure have not been confirmed. Moreover, hippocampal volume reduction also has been reported in nondepressed patients with cardiovascular disease. The finding of reduced hippocampal volume in depression, therefore, may simply reflect the high load of cardiovascular disease in these patients.

Elderly patients with vascular depression may show subcortical hyperintensities. These are areas within the white matter (neuron fiber tracts) and the subcortical grey-matter nuclei (neuron cell bodies) that are bright on T2-weighted MRI scans. They are associated with risk factors for cerebrovascular disease and may be areas of demyelination, local brain swelling, and small, old strokes. Elderly patients with major depression and bipolar patients of all ages have more extensive (in total area) subcortical white-matter hyperintensities than do age-matched healthy controls. The presence of subcortical hyperintensities in elderly depressed patients correlates with a greater sensitivity to the side effects of antidepressant medications, including delirium, a greater risk of developing tardive dyskinesia (a movement disorder)

from neuroleptic (antipsychotic) medication, and a longer recovery time from ECT.

MRS has been used to study several compounds in the brain in major depression and bipolar disorder. Phosphomonoesters, a component of cell membranes, have been found to be both elevated and decreased. Phosphocreatine, a high-energy phosphate, has been more consistently decreased. MRS of fluorine-containing drugs, such as some antidepressants, and of lithium provides brain concentrations of these compounds in patients under treatment and may eventually be helpful in guiding dosage adjustments to achieve maximum therapeutic response. SPECT and PET functional neuroimaging studies of major depression and bipolar disorder have shown decreased prefrontal cortical and anterior cingulate gyrus blood flow and glucose metabolism, although these findings have not been consistent. In addition, there have been inconsistent reversals of these abnormalities in treated patients; however, it does appear that successful antidepressant pharmacotherapy is associated with increased blood flow and/or metabolism in the prefrontal cortex, cingulate cortex, and/or the basal ganglia (caudate nucleus, globus pallidus, and putamen).

Brain Circuit Theories of Depression and Manic-Depression

Brain circuit theories of major depression and bipolar disorder all represent variations on the postulated involvement of certain areas of the frontal parts of the brain (frontal lobes) and their functional interconnections with deeper parts of the brain – the cingulate gyrus, basal ganglia, thalamus, and other structures, including hippocampus and amygdala. Several of these structures make up the limbic system, a phylogenetically older part of the brain that influences emotional coloration and behavioral reactivity. In a general sense, the frontal lobes of the brain mediate executive functions; that is, an individual's decision-making and behavioral actions based on a detailed evaluation of environmental demands, along with an appreciation of their historical context, and a coordinated affective/emotional component. Particular areas of the frontal cortex mediate executive behavior, social behavior, and motivation.

The underlying theme of the brain circuit theories of major depression and the depressive phase of bipolar disorder is that the cognitive dorsal prefrontal cortex cannot effectively modulate the ventral orbitofrontal and medial prefrontal cortex and the limbic system components of emotions, so that what in a normal individual would be an expression of sadness becomes magnified and prolonged into a major

depression when the interactive circuitry is not functioning properly. Ascending monoamine projections from the brainstem involving dopamine, norepinephrine, and serotonin set the tone in the emotional circuits comprising the prefrontal cortex, ventral striatum, mediodorsal thalamus, and projections back to the prefrontal cortex. When these delicate, unmyelinated, slow-conducting monoamine projections are damaged or rendered dysfunctional, monoamine control of the emotional circuits becomes abnormal.

Several distinct pathologic processes may cause such disconnection of the monoaminergic projections from their target neurons in prefrontal cortex and subcortical sites. These include loss-of-function polymorphisms of the BDNF gene, with resultant vulnerability to stress or glucocorticoids through reduced terminal arborization of monoaminergic axons; vascular lesions of the monoaminergic fibers in their passage through the midbrain and internal capsule; degenerative changes in brainstem monoaminergic cell nuclei as happens in Parkinson disease, Huntington disease, and Alzheimer disease; and functional impairment of the monoaminergic neurons by drugs such as reserpine, which prevent vesicular storage of the monoamine neurotransmitters, with resultant depletion of tissue monoamine concentrations. No matter which of these processes is operative, the final effect is loss of monoamine control over activity in the prefrontal-subcortical emotion circuits and the appearance of a primary or secondary depressive syndrome. In these syndromes, the expressed symptoms are very similar, regardless of the underlying pathology. The aforementioned reductions in resting prefrontal cortical blood flow and glucose metabolism, as determined by functional neuroimaging with SPECT, PET, and fMRI support this brain circuit theory. Likewise, increased activity in these same regions is seen when negative emotional processing tasks are performed by depressed patients.

Psychological Testing in Depression and Manic-Depression

Many general psychological tests contain questions pertaining to mood, and these tests usually give a score that indicates the degree of depression. Because depression and manic-depression are often recognizable clinically, however, psychological testing is usually not done unless there are ancillary questions, such as the possibility of associated dementia or psychosis. Psychological testing also may be helpful in differentiating depressive pseudo-dementia from primary dementia. In a patient presenting with dementia, an indication of depressive features by psychological testing, which may not have been apparent clinically,

usually signals the need for antidepressant treatment. In such cases, following successful treatment of the depression, the dementia also should have improved, which can be determined by repeat psychological testing.

There also are some rating scales designed specifically to quantitate depression. The Hamilton Rating Scale for Depression (HAM-D), which is scored by the person examining the patient, is the gold standard for clinical trials of antidepressant efficacy. Self-rated scales such as the Beck Depression Inventory (BDI) and the Carroll Depression Scale (CDS) also are used. The HAM-D tends to emphasize the physiological aspects of depression, such as sleep and appetite disturbance and physical symptoms of anxiety. The BDI emphasizes the cognitive component of depression; that is, how the person thinks about him- or herself when depressed. Short, self-rated depression screening scales also are used in epidemiologic studies and in primary medical care settings.

Treatment of Major Depression and Manic-Depression

The first issue in the treatment of patients with major depressive and bipolar disorder is to assess their immediate personal safety in light of the severity of their illness. For depressed patients, this always includes an assessment of their suicide potential. For manic patients, it includes not only an assessment of their suicide potential, especially in mixed bipolar disorder, but also whether their behavior is harmful (e.g., excessive alcohol intake, buying sprees, sexual indiscretions, or foolish business decisions, as mentioned earlier). The most certain way to interrupt behavioral indiscretions and protect the individual from suicide attempts is hospitalization in a specialized psychiatric unit whose staff is trained in the care of such patients. If the patient resists hospitalization, an involuntary hold may be medically and legally justified. A locked psychiatric unit, which prevents the patient from leaving, may be necessary until the illness is sufficiently under control that the patient's better judgment returns.

The treatment of major depression and bipolar disorder almost always requires drug therapy with antidepressants and/or mood-stabilizing drugs. There are several chemical classes of antidepressant drugs, and they have specific pharmacological activities in the CNS. As previously mentioned, many of them block the transporters for norepinephrine and/or serotonin, which recycle the neurotransmitters from the synapse back into the nerve cells that released them. By blocking transporter uptake, antidepressants increase synaptic neurotransmitter concentrations.

The time course for a full clinical response to antidepressant drugs is 3–6 weeks, even though their pharmacological effects occur within 12–24 h. Often, improved sleep may be an early sign of response to medication, especially with antidepressants that have sedative side effects. Objective signs of improvement usually precede the patient's feeling better; for example, the person may be sleeping and eating better, may have more energy and a higher level of activities, and may be speaking more cheerfully, but he or she still may be complaining about feeling as depressed as before. The subjective depressed mood is often the last aspect of the illness to improve. Because the subjective experience of depression is so psychologically painful and stressful, it is very important that a patient with suicide potential not be released from the hospital until he or she is in sufficient behavioral control to no longer be a suicide risk after discharge.

As mentioned, some antidepressants are specific uptake inhibitors of norepinephrine and others of serotonin, but it is not possible to predict which depressed patient will respond to which antidepressant. This is most likely on the basis of the physiological interactions of neurotransmitter systems and, as previously indicated, the fact that almost all antidepressants result in downregulation of postsynaptic noradrenergic receptors and induction of BDNF over the same time course as clinical improvement occurs. Antidepressants therefore are usually chosen on the basis of their side effects and cost, those under patent being more expensive than those available in generic form. Many of the older antidepressants have prominent side effects, such as causing dry mouth, blurred vision, and especially changes in the electrical conduction system of the heart. This last side effect can be particularly dangerous in accidental or deliberate drug overdose.

The class of antidepressant drugs currently in greatest use is the serotonin uptake inhibitors (SUIs). The first SUI accepted for clinical use in the United States was fluoxetine (Prozac). The SUIs may not be quite as effective as the original tricyclic and monoamine oxidase inhibitor antidepressant drugs, especially in severe depression, but they have fewer side effects, especially cardiac, which makes them generally safer drugs to use. They do have other side effects that must be considered, including weight gain, decreased sexual drive, akathisia (inner restlessness), and some increased risk of suicidal thinking or gestures. Although it has not been established that antidepressant drugs provoke completed suicides, regulatory warnings emphasize that patients must be followed closely for this risk during the early weeks of treatment.

Recent studies have shown that the efficacy of the SUIs in the broad, heterogeneous group of patients diagnosed with major depression is modest at best. The Number Needed to Treat (NNT) is a standard therapeutics measure that denotes the number of patients who must receive a drug for one drug-attributable therapeutic outcome to be achieved, that is; over and above the placebo response rate. For the SUIs, the NNT ranges from five to twelve, whereas the NNT for the early tricyclic antidepressant drugs in severe, hospitalized depressed patients was three. Recent studies also confirm that there is no significant difference in response or remission rates between SUIs and some other newer antidepressants vs. placebo in mild depression. The National Institute for Clinical Excellence (NICE) in Britain therefore has recommended that nondrug treatments be used first in mild depression.

A new class of antidepressant drugs that block synaptic reuptake of both norepinephrine and serotonin (e.g., venlafaxine and duloxetine) has recently appeared. The dual action of these drugs recapitulates the pharmacodynamic profile of original antidepressant agents such as imipramine, amitriptyline, and phenelzine, but with a greatly reduced side-effect profile. These dual-action drugs appear to be more effective than the SUIs in treating major depression. For example, in direct comparisons, the NNT for venlafaxine to produce remission is five, compared with ten for the SUIs.

The other major class of drugs used in mood disorders, especially in bipolar disorder, is the mood stabilizers. For manic patients, lithium is the most effective. Lithium is a metal ion, in the same class in the periodic table of elements as sodium and potassium. Lithium has a number of effects on neurotransmission in the CNS. It has a relatively narrow therapeutic index; that is, the blood concentrations at which lithium exerts toxicity are not very far above the concentrations required for its therapeutic effect. Therefore, patients taking lithium require frequent measurement of their circulating lithium concentrations, especially at the outset of treatment, to determine the daily dose necessary to achieve a therapeutic blood level. Lithium takes several weeks to achieve its full antimanic effect. It is a mood stabilizer rather than a pure antimanic compound, so bipolar patients who switch from mania into depression are usually continued on their lithium if an antidepressant is added.

For major depressive and bipolar patients, additional dimensions of their illnesses may suggest the need for other medications in addition to antidepressants and lithium. For example, prominent psychotic

features in either illness may call for an antipsychotic medication to be used concomitantly. For the treatment of depression, hormone supplements such as estrogens in women and thyroid hormone may be helpful. For the treatment of bipolar disorder, a number of anticonvulsant medications have been shown to be effective, often as augmentation of lithium treatment. Compounds such as carbamazepine, valproate, and lamotrigine are currently in use, and several newer anticonvulsants are being tested for their mood-stabilizing properties.

After the successful drug treatment of a first lifetime episode of major depression, continuation treatment at full dosage is advised for 9 to 12 months to prevent relapse. The slow reduction of the medication then is attempted. Patients who experience recurrent depression, particularly those who have had three or more lifetime episodes, require long-term antidepressant maintenance treatment at full dosage to prevent recurrences. Controlled trials have established that, even after 3 years of successful preventive drug treatment, 50% of such patients will have a recurrence within 6 months of stopping their medication.

Bipolar patients need to have medication adjustments made according to the frequency of their manic and depressive mood swings; it may take years for the timing of these cycles to be clearly understood. Both disorders should be viewed as chronic illnesses, often relapsing over a person's lifetime. If strenuous attempts at drug treatment of either disorder fail, ECT often will provide definitive relief of symptoms. Usually, 10 treatments are given, three per week. The patient may suffer some memory loss during and following the treatments, but this is short-lived, whereas the therapeutic effect can be remarkable, especially in patients resistant to drug therapy. Unilateral, brief pulse application of electrical current to the nondominant hemisphere can reduce these memory changes significantly. Maintenance ECT, often one treatment every month or so, can be useful to keep the person in remission from his or her illness.

In addition to pharmacotherapy and ECT, psychotherapies of different types, such as cognitive-behavioral therapy, often are useful to help the person change his or her lifestyle and manner of thinking about adversity. An improvement in self-esteem often results, which may protect against future episodes of depression or at least may reduce their severity.

Conclusion

Major depression and manic-depression (bipolar disorder) represent serious psychiatric illnesses. In

addition to interfering with occupational and social functioning, these illnesses put the sufferer at personal risk – a potential for suicide attempts in the case of depression and impulsive behaviors such as excessive alcohol intake, buying sprees, sexual indiscretions, and foolish business decisions in the case of a manic episode. Severe life stressors often precede a depressive episode, and both illnesses create their own stresses in the sufferer, including the psychological pain of depression and the untoward consequences of unrestrained manic behavior. Fortunately, there are effective pharmacological treatments that can produce remission in the majority of patients, and for those who do not respond to drug treatment, ECT is an excellent therapeutic modality. The neurological circuitry involved in mood disorders is being revealed, with the result that new treatment approaches are emerging.

Effects of the n-3 and n-6 Fatty Acids on Stress and Anxiety-like Behavior, Corticosterone, and Neurotransmission in Animal Experiments

Clinical Investigation of Fatty Acid Composition in Major Depression

The n-3 Fatty Acids in the Treatment of Depression

Glossary

<i>Cytokines</i>	A group of pleiotropic proteins produced from leukocytes in the immune system and from microglia and astrocytes in the brain in response to a wide range of stimuli such as antigens, microbial soluble factors, endotoxins, stress, neurotoxicity, and injury.
<i>Elevated plus-maze</i>	A maze that comprises two open and two closed arms, elevated from the floor. Rodents with anxiety will increase entries into and time spent in closed arms.
<i>Limbic system</i>	The brain area involved with involuntary functions, emotion, and behavior; includes the hypothalamus, hippocampus, amygdale, fornix, and stria terminalis.
<i>Mitogens</i>	Foreign substances to the body; induce macrophage and lymphocyte proliferation and cytokine releases.
<i>Monoamine</i>	General name for catecholamine and indoleamine neurotransmitters.
<i>n-3 and n-6 fatty acids</i>	Types of fatty acids, named for the position of the first double bond in the

carbon chain, starting at the methyl end of the molecule.

Neurotransmitters

Open field test

T helper 1 (Th1) cells and pro-inflammatory cytokines

T helper 2 (Th2) cells and anti-inflammatory cytokines

Chemical messengers released from neurons to excite or inhibit adjacent neurons. A test that provides a novel and stressful environment for animal behavior.

A subtype of T lymphocytes; produce cytokines that can trigger inflammatory response.

A subtype of T lymphocytes; produce cytokines, some of which can suppress Th1 functions and suppress inflammation.

Introduction

Cytokines, Stress, and Depression

It is well known that stress is a trigger for depression and that increases in stress- and anxiety-type symptoms are common in depressed patients. In the past 15 years, many studies have demonstrated that an increase in inflammatory response is associated with stress exposure and depressive illness. In human subjects, psychological stress significantly increases pro-inflammatory (but inhibit anti-inflammatory) cytokine production in patients responding to stress and anxiety. In depressed patients, increases in macrophage activity and the production of pro-inflammatory cytokines, complement, and some acute-phase proteins have been consistently reported. Conversely, more than 70% of volunteers or nondepressed patients showed severe depressive symptoms after receiving tumor necrosis factor (TNF)- α or interferon (IFN)- γ treatment. Furthermore, animal experiments have demonstrated that pro-inflammatory cytokines, such as interleukin (IL)-1 β , IL-6, and TNF- α can stimulate the hypothalamus to release corticotropin releasing hormone (CRH), which, via

adrenocorticotrophic hormone (ACTH), induces glucocorticoid (GC) secretion. Excessive secretion of GC may downregulate GC receptors in the hippocampus, which impairs the GC feedback system. Similar neuroendocrine changes also occur in depressed patients. From the neurotransmitter perspective, pro-inflammatory cytokines have been found to reduce both serotonin and norepinephrine availability to the brain, which is similar to levels observed in the depression. Thus, inflammation and cytokines may play an important role in stress and depression

The n-3 and n-6 Fatty Acids, the Immune System, and the Central Nervous System

Long-chain polyunsaturated fatty acids (PUFA) are synthesized from dietary precursors such as α -linolenic (n-3) and linoleic (n-6) fatty acids. The n-3 fatty acids include docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA); the n-6 fatty acids include arachidonic acid (AA) and dihomo- γ -linolenic acid (DGLA). These fatty acids are important components of membrane phospholipids in neurons, glial, and immune cells and are involved in many functions of the immune and central nervous system for the following reasons. First, changes in membrane fatty acid components may change receptor, enzyme, and peptide functions in the central nervous system (CNS) and immune system. Because a high proportion of proteins in the cell is actually embedded in the membrane, the quaternary structures of proteins and the final modeling and folding often depend on the precise nature of the lipid environment of that protein. Second, fatty acids can influence signal transduction. Neurotransmitters, hormones and cytokines hit a target and induce functional changes through activating phospholipases that then generate a wide range of cell signaling or signal transduction. Third, fatty acids and other lipids can switch on and off many different genes. In particular, by binding to peroxisome proliferator-activated receptors, fatty acids can switch on and off whole genetic programs involving the interaction of many different genes. Lipids or carbohydrates also modulate heat shock proteins, which aid the expression of mRNA and the synthesis of proteins. Fourth, fatty acids influence ongoing metabolic regulation. Several studies have revealed that phospholipids are undergoing constant remodeling, with key fatty acid components having half-lives of a few minutes.

In the immune system, the onset of autoimmune and inflammatory diseases has been related to an imbalance in the intake of n-3 and n-6 fatty acids. Inflammation is an important component of the early immunological response, whereas inappropriate

or dysfunctional immune responses underlie chronic inflammatory and autoimmune diseases. The n-6 PUFA AA is the precursor of eicosanoids that produce prostaglandins (PG), leukotrienes, and related compounds to activate macrophages, produce pro-inflammatory cytokines, and shift the response of T-helper type (Th)1 and Th2. Th1 cells trigger pro-inflammatory response, whereas Th2 cells suppress Th1 response. By contrast, high intakes of long-chain n-3 fatty acids (in fish oils) inhibit certain immune functions (e.g., antigen presentation, adhesion molecule expression, Th1 responses, and production of eicosanoids and pro-inflammatory cytokines). Moreover, a diet enriched with fish oil has been shown to ameliorate the symptoms of autoimmune disease in animal models and to protect against the inflammatory effects of endotoxins. Clinical studies have reported that oral fish oil supplementation has beneficial effects in rheumatoid arthritis and some asthmatics, supporting the idea that the n-3 fatty acids in fish oil are anti-inflammatory.

In the brain, 60% of weight is made up of lipids, of which the essential fatty acids (n-3 and n-6) are important membrane components. Free fatty acids that are released into the blood and then pass through the blood-brain barrier can act at specific binding sites in the brain. Changes in the phospholipids content of the neuronal membranes directly affect membrane viscosity and fluidity, which may cause abnormalities in neurotransmitter binding and reuptake, receptor density and affinity, and hormone secretion. In the CNS, n-3 and n-6 fatty acids have been shown to fulfill different roles and to act as antagonists and agonists of one another. The n-6 fatty acid AA enhances the release of glutamate neurotransmitter, inhibits neurotransmitter uptake, stimulates stress hormone secretion, and enhances synaptic transmission. In the immune system, AA can trigger an inflammatory response and increase oxidants in the brain. Therefore, AA may contribute to inflammatory and oxidative toxicity in neurodegenerative diseases. By contrast, n-3 fatty acids have been found to compete with n-6 fatty acids. EPA can protect neurons from inflammation and oxidants. However, n-3 and n-6 fatty acids also interact with and synergize one another.

Abnormal concentrations of or metabolism of n-3 and n-6 fatty acids has been found in depression and follow stress exposure. The most recent findings have shown that n-3 fatty acids can modulate many inflammation-induced changes in the CNS. This article reviews the changes in fatty acids in stress and depression, clinical treatment with n-3 fatty acids in depressed patients, and the mechanism by which n-3 fatty acids modulate the behavior,

Figure 1 The relationship between stress and neuroendocrine system. The n-6 fatty acids are precursors of prostaglandin E2 (PGE2) and pro-inflammatory cytokines that can stimulate the HPA axis to release stress hormone glucocorticoids. Many studies have demonstrated that this hormone can change neurotransmission and cause stress/depressive symptoms. In the brain, n-6 fatty acids may activate microglia/astrocytes and increase inflammatory response, which may also change neurotransmission. The n-3 fatty acids can compete with the effect of n-6 fatty acids. Several studies have shown that n-3 fatty acid intake can reduce n-6 fatty acid contents in the brain. Furthermore, n-3 fatty acids have been reported to have anti-inflammatory effects, protect neurons, and modulate neurotransmission, such as serotonergic and noradrenergic systems. EPA has been also found to suppress glucocorticoid release, which may result from EPA inhibition of PGE2 and pro-inflammatory cytokine productions.

hypothalamic-pituitary-adrenal axis, immune response, and neurotransmitter systems in experimental studies. The relationship among fatty acids, stress, and depression is shown in [Figure 1](#).

Stress and Fatty Acids in Human Studies

Several studies in university students have shown that psychological stress can induce the release of pro-inflammatory cytokines, such as IFN- γ , TNF- α , and IL-6 from mitogen-stimulated blood. In addition, increased pro-inflammatory cytokine production is positively correlated with stress and anxiety scores, whereas the synthesis of the anti-inflammatory cytokines IL-10, IL-4, and IL-5 are negatively correlated with these scores. As already mentioned, the n-3 and n-6 fatty acids differentially modulate an inflammatory response. For example, an imbalance between the n-6 to n-3 fatty acid ratio may predict a greater production of pro-inflammatory cytokines in response to psychological stress. In support of this, a study measured cytokine release from mitogen-stimulated whole blood culture and the concentration of n-3 and n-6 fatty acids in the serum of university students a few weeks before, a few weeks after, and 1 day before a difficult oral examination. Academic examination stress markedly increased stimulated the production of IFN- γ , TNF- α , and IL-10 and increased the ratio of IFN/IL-5 (a marker of Th1 or Th2 cell activity) in subjects with a lower serum concentration of n-3 fatty acids on the day before the examination compared to pre- and post-examination conditions. The increases in these pro-inflammatory cytokines were negatively correlated with the ratio of n-6 to n-3 fatty acids, and

decreases in pro-inflammatory cytokine production occur in the subjects with a low n-6 to n-3 ratio. These results demonstrate that psychological stress induces pro-inflammatory and Th1-like response in subjects with higher stress/anxiety scores. An imbalance in the levels of n-3 and n-6 fatty acids appears to predispose humans toward an exaggerated pro-inflammatory and Th1-like response.

Antistress effects have been also found in DHA-treated human subjects. For example, 41 students took either DHA-rich oil capsules containing 1.5–1.8 g DHA day⁻¹ or control oil capsules containing 97% soybean oil plus 3% fish oil for 3 months in a double-blind fashion. They took a psychological test (P-F Study), Stroop test, and dementia-detecting test at the start and end of the study. The study started at the end of summer vacation and ended in the middle of a period of mental stress, such as the final examination. In the control group, aggression against others in P-F Study was significantly increased at the end of the study as compared with that measured at the start, whereas it was not significantly changed in the DHA group. DHA supplementation did not affect the Stroop and dementia-detecting tests. Thus, DHA intake prevented aggressive behavior from increasing at times of mental stress. This finding might help to understand why fish oils prevent coronary heart disease.

Sympathoadrenal activation is postulated to be involved in the pathogenesis of heart diseases and may be inhibited by n-3 fatty acids. The effects of a diet supplemented with n-3 fatty acids on the stimulation of the sympathetic nervous system and of stress hormones elicited by a mental stress were evaluated.

Seven human volunteers were studied on two occasions, before and after 3 weeks of supplementation with 7.2 g day⁻¹ fish oil. On each occasion, the concentrations of plasma cortisol, catecholamines, energy expenditure (indirect calorimetry), and adipose tissue lipolysis (plasma nonesterified fatty acid concentrations) were monitored in basal conditions followed by a 30 min mental stress period (mental arithmetics and Stroop test) and a 30-min recovery period. In control conditions, mental stress significantly increased heart rate, mean blood pressure, and energy expenditure. Stress also markedly increased plasma adrenaline, cortisol and nonesterified fatty acids. After 3 weeks of a diet supplemented with n-3 fatty acids, these changes induced by mental stress were all significantly attenuated. This result suggests that n-3 fatty acids inhibit the adrenal activation elicited by stress, presumably through effects exerted at the level of the CNS.

Effects of the n-3 and n-6 Fatty Acids on Stress and Anxiety-like Behavior, Corticosterone, and Neurotransmission in Animal Experiments

The effect of fatty acids on stress in rodents has been investigated in the following experiments. In the n-3 fatty acid-deficient mice, the role of n-6 fatty acids in stress response was compared to mice fed a normal diet. Mice fed 1.2% linoleic acid (a major dietary n-6 fatty acid) for two generations showed a markedly decrease in exploration in open field test and a decrease in time spent in open arms of the elevated plus-maze. A significant reduction in the n-3 fatty acid concentration was also found in the brain of these mice. After feeding with 0.5% α -linolenic acid (a source of n-3 fatty acids) for 8 weeks, the mouse behaviors were partially reversed.

The n-3 fatty acid DHA has been also found to attenuate the effect of stress in an animal model. Rats subjected to a psychosocial stress, such as isolation or an intermittent-feeding schedule, show a significant increase in heart rate, cardiac contractility, and cardiac norepinephrine concentration, which are blocked by DHA-enriched diet. The fatty acid composition of adrenals was significantly related to the fatty acid intake, particularly the neutral lipid fraction, which incorporated a large amount of DHA. Another experiment determined whether DHA affects stress responses in rats on several behavioral tests. Female rats were fed a diet deficient in n-3 fatty acid from mating through pregnancy and lactation. Male pups fed the same diet as their dams were then studied. The effects of dietary (n-3) fatty acid

deficiency and supplementation with DHA on psychological stress (as assessed by behavior in the elevated plus-maze) and conditioned-fear stress were investigated. The n-3 fatty acid-deficient rats spent significantly less time in the open arms of the plus-maze, suggesting increased anxiety; after 1 week of supplementation with DHA, they showed a significant improvement. The paired effects of DHA and CRH on stress were then evaluated. An intracerebro-ventricular (ICV) infusion of CRH under resting conditions was shown to have stress-inducing effects on behavior, such as decreases in rearing, smelling, and feeding and increases grooming in a novel environment open field. The DHA diet significantly improved these stress-induced behaviors. Finally, conditioned fear was induced by 40-min forced exposure to a cage in which the rat had experienced foot shocks 1 day before. Freezing behavior was dramatically suppressed by the supplementation of DHA, even 48 h after the conditioning treatment. Furthermore, the effect of DHA on the conditioned fear stress response was maintained over a long-term period. The ICV pretreatment of rats with bicuculline, a GABA_A receptor antagonist, enhanced the conditioned-fear-induced freezing time in a dose-dependent fashion in the n-3 fatty acid-deficient animals. Significantly, the DHA-supplemented group was not affected by the pretreatment with bicuculline. From these findings, it is concluded that the involvement of DHA in stress responses may act via a GABA_A receptor-mediated mechanism.

As mentioned previously, pro-inflammatory cytokines can stimulate the HPA axis to produce glucocorticoids and also induce stress and anxiety-like behavior. In the novel and stressful environment of the open field apparatus, the ICV administration of IL-1 β in rats reduced locomotor activity, exploratory behavior, and central zone entry but increased grooming behavior. In elevated plus-maze, IL-1 β decreased number of entries into and time spent in the open arms, which indicate an increase in anxiety-like behavior. These changes were correlated with the increase in the blood concentration of corticosterone. Feeding rats for 7 weeks with a diet containing rat basal food, supplemented with 0.2 or 1% n-3 fatty acid EPA led to significant increases in locomotor activity and exploration following the ICV administration of IL-1 β ; the grooming score was also decreased in the treatment with IL-1 followed by EPA. IL-1-induced anxiety-like behavior in the elevated plus-maze was also reversed by the diets enriched with 0.5 or 1% EPA. The elevated corticosterone level induced by IL-1 β was attenuated by 0.5 and 1% but not by 0.2% EPA.

With regard to changes in neurotransmission, several investigations have reported that following acute central administration of IL-1 β , changes in monoamine neurotransmitters and their metabolites were similar to changes observed after stress exposure. These changes include increases in the metabolism of serotonin, dopamine, and norepinephrine. If stress consistently increases the metabolism of these monoamines, a depletion of these neurotransmitters and reduction of these neurotransmitter functions may occur. Indeed, subchronic and central administration of IL-1 β has been found to reduce norepinephrine and serotonin concentrations in the limbic system, a similarity that has been reported to occur in depression. In addition, lower cerebrospinal fluid (CSF) concentrations of serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) and the dopamine metabolite homovanillic acid (HVA) are correlated with depressive mood and suicidal ideation in depressed patients. However, what causes the neurotransmitter deficiency is remain elusive. Recent research has shown that the catabolism of tryptophan (a precursor of serotonin) is stimulated under the influence of stress and inflammation by the induction of the enzymes tryptophan pyrrolase and indoleamine 2,3-dioxygenase (IDO). Thus, the reduction in blood concentration of tryptophan under these circumstances leads a reduction of formation of brain serotonin. Furthermore, low levels of n-3 fatty acids and a high n-6 to n-3 fatty acid ratio were correlated with low CSF concentrations of 5-HIAA and HVA. In the clinical study, EPA has been found to significantly improve depressive symptoms, which may be related to the modulation of n-3 fatty acids on these neurotransmitters. Indeed, animal experiments have shown that EPA can increase serotonin and dopamine synthesis, and attenuate the IL-1-induced changes in the noradrenergic and serotonergic systems. These results provide neurochemical mechanism by which EPA may effectively treat depressive illness.

As previously mentioned, the n-3 and n-6 fatty acids are agonist and antagonize one another to maintain the homeostatic balance. Different combinations and ratios of n-3 and n-6 fatty acids have been studied in inflammation or stress-induced rat models. For example, the effect of 0.5% EPA, n-6 fatty acid γ -linolenic acid (GLA), AA, the combination of EPA and AA, and EPA and GLA on changes in IL-1-treated rats has been studied. The GLA had little effect on the IL-1-induced changes in behavior and the rise in the corticosterone concentration. Similarly, the n-6 fatty acid AA had no effect on these changes induced by IL-1. However, AA alone enhanced the basal inflammatory response, raised the serum corticosterone

concentrations, and induced anxiety-like behavior in the elevated plus-maze. Even though the prostaglandin E2 (PGE2), derived from AA, was suppressed significantly, the combination of EPA and GLA did not attenuate the behavioral and corticosterone changes following the administration of IL-1. Neither EPA and AA combination attenuated both the inflammatory and behavioral changes induced by IL-1. Following the ICV administration of IL-1, the decreased norepinephrine (NE) and serotonin, and increased dopamine (DA) and serotonin turnovers in several brain regions were attenuated by EPA, whereas the EPA and GLA combination reversed some, but not all, of these changes. These results also showed that only the combination of EPA and GLA in a one-to-one ratio has stronger anti-inflammatory effects.

In another experimental study, the effect of a diet of the n-3 and n-6 fatty acids was reported in two stress models, namely cortisol injection and immersion in a 10°C saline bath (cold stress). Compared to control rats (saline injection or immersion in 20°C saline bath), the cortisol injection or cold stress largely increased the blood concentration of cortisol and cholesterol. The mixed diet containing α -linolenic (n-3 fatty acid; 0.92 g ml⁻¹) and linoleic (n-6 fatty acid; 0.90 g ml⁻¹) for 3 weeks reversed these increases induced by cortisol or cold stress. It has been also reported that the most effective ratio of n-6 to n-3 fatty acids is four to one. The interaction between n-3 and n-6 fatty acids, and the mechanism whereby some combinations have different effects, needs to be further studied.

Clinical Investigation of Fatty Acid Composition in Major Depression

Epidemiological studies in various countries suggest that decreased n-3 fatty acid consumption correlates with the increasing rates of depression. However, so far there has been no direct measurement of PUFAs in the postmortem brains of depressed patients. Thus, current information depends on the data from measurements in plasma and erythrocyte membranes. In a study, containing 36 patients with major depression, 14 patients with minor depression and matched healthy controls, it was shown that patients with major depression had significantly lower total n-3 fatty acids in cholesteryl esters and lower EPA in both cholesteryl esters and phospholipids. There was also a higher ratio of AA to EPA in patients with major depression. In addition, the level of EPA in cholesteryl esters and plasma was negatively correlated with the score on the Hamilton Depression Rating scale (HAM-D).

In another clinical investigation, the erythrocyte membrane phospholipid level and dietary intake of polyunsaturated fatty acids were studied in depressed patients and their matched controls. A significant depletion of erythrocyte membrane n-3 fatty acids was found. Both erythrocyte membrane levels and diet intake of n-3 fatty acids were negatively correlated with the severity of depression. However, antidepressant treatments had no significant effect on the fatty acid levels of the cholesteryl esters. There is also evidence that pregnancy leads to a depletion of maternal serum n-3 fatty acid DHA and that, after delivery, the maternal serum DHA steadily declines further. One study investigated whether the postpartum fatty acid profile of maternal serum and cholesteryl esters differs in women who develop postpartum depression compared to controls. The fatty acid composition was compared shortly after delivery in 10 women who developed postpartum depression and 38 women who did not. After delivery, DHA and the sum of the n-3 fatty acids in phospholipids and cholesteryl esters were significantly lower in the group of mothers who developed a postpartum depression. The ratio of n-6 to n-3 fatty acids in phospholipids was significantly higher in the postpartum depressed group compared to the controls. Thus, the abnormalities in fatty acid status previously observed in major depression are now also confirmed in postpartum depression. These results indicate that pregnant women who are at risk of developing postpartum depression may benefit from a prophylactic treatment with n-3 PUFAs, such as a combination of EPA and DHA.

The n-3 Fatty Acids in the Treatment of Depression

Clinical investigations have demonstrated that EPA can effectively treat depression. In a double-blind placebo-controlled trial, EPA was added to ongoing antidepressant therapy. Patients with major depression were allocated at random to take either 2 g daily ethyl-EPA or placebo for 4 weeks. The treatment effects were assessed using HAM-D. There was a strong and highly significant treatment effect favoring EPA over the placebo. More recently, a dose-ranging study of ethyl-EPA was conducted in primary-care patients who suffered from treatment-unresponsive depression. The patients were randomly allocated to take ethyl-EPA (1 g, 2 g, or 4 g daily, or a matching placebo) for 12 weeks. Mood was assessed using the HAM-D, Montgomery-Asberg Depression Rating Scale (MADRS), and Beck Depression Inventory (BDI). The greatest improvement was shown in the

EPA 1 g day⁻¹ group compared to the 2 or 4 g groups. All three factors of the HAM-D, 9 of 10 items on the MADRS, and 20 items of BDI showed significant differences between groups taking ethyl-EPA and the placebo, with a particularly large treatment effect on BDI symptoms of sadness, pessimism, inability to work, sleep disturbance, and loss of libido. Adverse effects were equally distributed between the placebo and 1 g EPA. However, in two clinical studies, DHA at a dose of 1.15 or 2 g was found to be no better than a placebo. Nevertheless, these results strongly suggest that EPA may be an effective antidepressant that lacks many adverse effects that are associated with conventional antidepressants.

In conclusion, the n-3 and n-6 fatty acids play different roles in inflammation, stress, and depression; the n-3 fatty acids decreased them, whereas the n-6 fatty acids increased them. The understanding of this new research area is still limited, and most mechanisms are unknown. Future studies should consider (1) the interaction between lipids and neurotransmitter receptor functions, (2) the interaction between membrane n-3 and n-6 fatty acids, (3) the ideal balanced diet for the n-3 and n-6 fatty acids in normal people and in patients with various diseases.

Stress Models of Depression

Conclusion

Glossary

<i>Anhedonia</i>	The loss of the capacity to experience pleasure, a core symptom of depression.
<i>Intracranial self-stimulation</i>	An experimental technique whereby a small electrical charge can be delivered directly into the substance of the brain of an awake, freely moving subject via an implanted electrode.
<i>Limbic system</i>	An arrangement of anatomically related brain structures that are hypothesized to play a critical role in the production and regulation of emotion.
<i>Mesolimbic dopamine projection</i>	A grouping of dopamine-secreting neurons that arise in the midbrain to innervate a range of higher brain structures that includes the nucleus accumbens in the ventral striatum.
<i>Validity</i>	The authenticity of a presumed relationship between two separate events or observations.

Validity and Utility of Depression Models

Depression models serve many different purposes and the inherent value of each is determined by the

specific aims and utility of the individual model. It is therefore critical to establish the explicit purpose intended for that preparation in order to determine its validity and utility. There are several scholarly and comprehensive reviews of procedural details and the relative merits of different animal models of depression that achieve this purpose (see Further Reading). Although depression models can be categorized and evaluated according to almost any aspect of their construction, there is general agreement on the utility of addressing different aspects of validity separately. The validity spectrum includes construct validity and the related concepts of discriminant and convergent validity, predictive validity, face validity, and etiological validity.

The construct validity of a model refers to the accuracy with which the model replicates the key abnormalities or phenomena under study within the clinical condition. For example, if a model somehow encapsulated a blunting of a capacity to experience pleasure, it could be considered to demonstrate substantial construct validity with respect to anhedonia, one of the defining features of clinical depression. Of course, to comment on construct validity there is an implicit requirement that the target phenomenon be well defined, either behaviorally or neurobiologically, within the clinical state. For many aspects of depressive disorders, this remains problematic. Nevertheless, judgments can be made as to whether observations in a model appear to bear a meaningful relationship to those of the clinical disorder. Models with strong construct validity represent attempts to replicate core clinical phenomena in a laboratory context and are driven by specific hypotheses concerning the etiology, clinical features, and pathophysiology of depression. Such models are frequently labeled theoretical models.

A closely related concept to construct validity is etiological validity, whereby the circumstances or events that lead to development of the target phenomenon in the model are substantially similar to those generating the same phenomenon in the clinical disorder. Etiological validity can usefully be considered a

refinement of the more general concept of construct validity. For many depression models, the experimenter-initiated intervention is considered to mimic an environmental event of causal significance. However, such assumed relationships are problematic because the causal antecedents of depressive disorders, including those that are best studied, genetic vulnerability and stress, remain poorly defined.

The predictive validity of a model refers to its ability to correctly discriminate between interventions that are known to have effective antidepressant properties. Typically, these interventions are drug treatments. Depression models with strong predictive validity are widely used within the pharmaceutical industry to screen new molecules for potential antidepressant activity, hence the term assay model. The most potent models within this category are capable of discriminating pharmacologically diverse chemical antidepressant treatments with few false positive or negative results. For a strong assay model, there is no requirement that aspects of the preparation bear meaningful relationship with features of the clinical disorder.

The face validity of a model is whether specific features of the model bear resemblance to discrete aspects of the clinical disorder, that is, whether a phenomenological similarity exists, irrespective of whether there is a plausible or established theoretical relationship between the two observations. In this respect, face validity can be differentiated from construct validity. When two or more depression models are being compared with one another, regardless of whether they are theoretical or assay, it is possible to comment on the degree to which observations from each appear to reflect aspects of the same construct. Hence, two or more different models may demonstrate convergent or discriminant validity. Convergent validity is the degree to which the same aspect of a single phenomenon or construct can be accessed and quantified by different models, whereas discriminant validity is the capacity of a model to measure different aspects of a single target phenomenon from those measured by related models. All models can be judged on the degree to which the target phenomena can be reproduced within and between studies – the reliability of the model. In the absence of reliability, no model can be considered to have utility. Hence, both validity and reliability are essential for any animal model of depression.

Stress and Depression

An enduring clinical literature suggests that individual vulnerability to stress and subsequent predisposition to develop certain disease states, notably

depression, are related, at least in part, to a history of early environmental adversity. Exposure to early trauma, for example sexual and physical abuse or other types of early disadvantage, can increase several-fold the risk of being diagnosed with a depressive illness in adulthood. Similarly, the onset and recurrence of adult depression can reliably be predicted by the presence of environmental stressors, often labeled life events. Some individuals may have a genetic propensity to select themselves into high-risk environments, but epidemiological studies using identical and nonidentical twins have shown that there is still a substantial causal relationship between stressful life events and depression. However, this relationship is greatest for the first episode and seems less important in recurrent episodes.

Neurotoxic Effects of Stress-Related Hormones

In humans and other animals, hypothalamic-pituitary-adrenal (HPA) axis activation leads to the release of glucocorticoid hormone (cortisol in humans and corticosterone in other species) from the cortex of the adrenal glands. Glucocorticoid hormones are released in response to a wide variety of psychological and physical stressors and represent a core component of adaptive responsiveness to environmental change and threat. However, high levels of circulating glucocorticoids may have a detrimental effect on brain circuitry and function particularly at certain stages of development. Clinical studies have consistently implicated abnormalities in the regulation of key neuroendocrine responses to stress in a proportion of patients with depression, with a hyperactivity of the HPA axis that is probably driven by hypersecretion of the hypothalamic peptide corticotropin-releasing hormone (CRH). Certain areas of the brain, including parts of the hippocampal formation, are more sensitive to damage from high levels of glucocorticoids.

Depression-Related Brain Pathology

Depression has been associated with abnormal function and/or pathological changes in several cortical, limbic, and striatal brain structures. There is an extensive amount of evidence suggesting alterations in the anterior cingulate cortex in mood disorders and also the orbital and dorsolateral regions of the prefrontal cortex. Two other structures within the temporal lobe, the hippocampal formation and the amygdala, show consistent reductions in size in major depression. There are close anatomical associations among all these structures, which form part of

Maclean's concept of the limbic system, which acts to integrate emotional expression with visceral and endocrine responses. Although support for the notion of a specific neural basis for emotion and motivation has accrued steadily from subsequent experimental, accidental, and therapeutic lesion studies in animals and humans, it is less clear whether the changes seen in the brains of patients with a diagnosis of depression can be specifically related to different symptoms that they show. The reduction in hippocampal gray matter may correlate with the severity and duration of illness and may also be responsible for some of the cognitive impairments seen in severe depression. However, some studies suggest that a decrease in hippocampal volume may be a specific marker of depression diagnosed in patients with a history of early trauma. Abnormalities in areas of the prefrontal cortex have been linked with the failure to anticipate positive outcomes or increased sensitivity to negative outcomes.

Behavioral Correlates of Depression

Depression is a very heterogeneous disorder, and those affected may display very different symptom clusters. Some patients may have pervasive symptoms of negative affect and anxiety, whereas others have a more prominent lack of positive affect. This becomes important when we consider which animal behaviors to assess when trying to model the disorder. Much emphasis has been placed on the capacity for stress to reduce or impair the performance of behaviors that serve to bring animals into contact with key stimuli or appetitive reinforcers within their environment. Engagement with such stimuli is inferred to convey pleasant or pleasurable hedonic consequences. Reduced engagement is generally interpreted as evidence that the stimuli no longer confer such consequences, at least to the same degree, and this has been deemed comparable to anhedonia, a core feature incorporated in current psychiatric diagnostic and classification systems of depression.

Anatomy of Reward

Research during the 1970s and 1980s identified the mesolimbic dopamine projection as a key component of neural circuitry mediating the psychological construct of reward. This pathway arises from cells bodies located in the ventral tegmentum in the midbrain, projecting upward and forward to the amygdala, lateral septum, bed nucleus of the stria terminalis, hippocampus, and nucleus accumbens (a component of the ventral striatum). On its journey forward, the

mesolimbic dopamine system passes through the lateral hypothalamus via a thick cable of fibers known as the medial forebrain bundle. Appetitive reinforcers (a term used to describe pleasurable hedonic consequences), including biologically meaningful stimuli such as food, sex, and drugs of abuse (e.g., cocaine and heroin), are dependent on the functional integrity of the mesolimbic projection system for their behavioral effects. Such appetitive reinforcers elicit approach behavior and contact. Thus, the nucleus accumbens, a structurally defined subregion of the ventral striatum, where ascending dopaminergic neurons synapse with intrinsic striatal neurons and descending glutamatergic projects from limbic cortical structures (such as the hippocampus, amygdala, and prefrontal cortex), represents a critical locus for the processing and execution of goal-directed behavior. Interference with dopaminergic transmission, either by lesioning the cell bodies in the midbrain or by the local administration of dopamine receptor antagonist drugs, leads to a profound disruption of a range of rewarded behaviors, including intracranial self-stimulation (ICSS), the self-administration of psychostimulant drugs of abuse (e.g., cocaine and amphetamine), and responding for primary and secondary reinforcers. In addition, the local infusion of dopamine receptor agonist drugs into the nucleus accumbens and the mesolimbic dopamine system are widely believed to represent the critical site through which drugs of abuse exert their reinforcing and addictive effects.

Stress Models of Depression

There are many experimental demonstrations of the capacity for stress to disrupt, or at least modify, behavior directed toward positively reinforcing stimuli. In this article, we focus on those that have held the greatest promise as valid animal models of depressive disorder.

Learned Helplessness

This is perhaps the best-known stress model of depression but it is covered in detail elsewhere (see *Learned Helplessness*).

Inescapable Foot Shock and Intracranial Self-Stimulation

Early research supporting the existence of specific reward or pleasure circuits in the brain came from studies showing that electrical stimulation of areas of the hypothalamus led to a powerful augmentation of approach behavior and vigorous self-administration of electrical current. Subsequent studies identified the

mesolimbic dopamine system, which passes through the lateral hypothalamus as the medial forebrain bundle, as the key component of this system. A specific hypothesis that linked human depressive behaviors with dysfunction of brain reward pathways was formulated. This hypothesis has been extensively tested in a series of experiments evaluating the interactions among responding for rewarding electrical brain stimulation, stress, and antidepressant drug administration. Rats demonstrate regional specificity within the brain for stress-induced decrements in responding to ICSS, most notably within the terminal fields of the mesolimbic and mesocortical dopamine projections. Exposure to unpredictable electric foot shock induced a profound and enduring reduction in responding when ICSS electrodes were sited in the ventral tegmentum, nucleus accumbens, and medial prefrontal cortex, but not in the adjacent dorsal striatum. This regional specificity exhibited a close anatomical concordance with structures known to respond to stress with alterations in dopamine function. Furthermore, chronic administration of the prototypical chemical antidepressant drug desmethylimipramine (DMI) prior to stress exposure significantly minimized the subsequent ICSS performance deficits. These data have been interpreted as demonstrating beneficial, or protective, effects of antidepressant drugs on the neural responses to stress, specifically in areas that are critically involved in the integration of behavioral responses to reward. However, additional studies employing different drug treatments, different electrode placements, and different strains of rat and mice have generated somewhat variable results.

Behavioral Despair

Also known as the Porsolt test, the forced-swim test (FST) involves forcing rats (or mice) to swim in a tall water-filled cylinder from which there is no escape. The water is sufficiently deep to preclude the animals from resting its limbs or tail on the bottom. When placed in this apparatus for the first time, the animal swims vigorously to maintain its head above water. With appreciation of the inescapable nature of its predicament, attempts to escape from the cylinder rapidly cease. Thereafter, the animal adopts an immobile posture that has been interpreted as a theoretical analog of hopelessness with respect to the possibility for escape. With repeated testing, the time to the onset of immobility decreases in control animals, and this has been interpreted as a theoretical analogue of learned helplessness. Exposing animals to the FST has also been reported to cause some neurochemical changes that are consistent with a depressogenic phenotype. For example, it can transiently reduce

serotonin and norepinephrin levels in both cortical and limbic structures and alter the sensitivity to CRH. Although there are obvious problems with the construct validity of this model, behavioral despair enjoys one of the most impressive records of all depression models with respect to pharmacological sensitivity and specificity. Hence, this model enjoys impressive predictive validity. The question of what exactly this model measures remains unanswered. Whereas the other stress-based models described here demonstrate altered responding toward rewarding stimuli, this test reflects something quite different. Although an operational definition of the phenomenon is simple, a description of the relationship to human affective disorder is not.

Chronic Unpredictable Mild Stress

In an attempt to design models with greater face and etiological validity, several different procedures have been devised that employ the sequential presentation of relatively mild stressors to rats or mice. In these models, the effects of stress are usually quantified by the degree to which they alter the intake of drinking solutions that are preferred over standard drinking water under normal circumstances. Katz and colleagues first explored the effect of unpredictable exposure to different types of stressors, including electric shock, cold swim, water deprivation, and shaker stress, and observed that rats failed to increase fluid intake when saccharin was added to their drinking water. This work was extended by Willner and colleagues, who put the emphasis on the sequential exposure to what they considered mild stressors such as periods of strobe lighting, food and water deprivation, cage tilting, and enforced group housing. These paradigms were reported to produce a loss of preference for or reductions in the absolute intake of sucrose, saccharin, and saline solutions. The behavioral deficits seen with chronic mild stress are reputed to respond to the chronic administration of chemical antidepressant drugs. However, like some other animals models of depression, there have been significant problems establishing these procedures reliably in different laboratories. The behavioral effects are at best modest, and large numbers of subjects are required. Many studies have also failed to include appropriate control measures.

Social Stress Models

This group of models relies on a different approach, disturbing the social environment either during early or later life. These manipulations are potent but naturalistic stressors. They would seem to have considerable etiological validity, although there is still some

debate over the degree to which stress has a causal role in depressive illness.

The disruption of mother–infant bonding or of peer bonding in young social animals generates a constellation of acute and chronic behavioral changes that resemble human depression and vulnerability to depression, respectively. Across a broad range of species, responses to separation follow a predictable time course with definable phases. Initially, the infant displays so-called protest behaviors that include increased locomotor activity and vocalization. This subsides in time and is generally replaced by a second phase that is characterized by locomotor inactivity and an apparent disinterest in motivationally salient external environmental stimuli, so-called despair. Depending on the species studied, there may also follow a third phase of detachment, during which the infant displays indifference to being reunited with its mother and/or peers. Social behaviors in adulthood are often profoundly abnormal in such animals. There is considerable cross-species generality of this bi- or triphasic response to social separation, suggesting that it may be hardwired in the brains of many social animals.

Nonhuman primates In the light of their phylogenetic proximity to humans, their advanced cognitive capacity, and their complex social structures, studies in monkeys have provided the bulk of the behavioral and neurobiological data in support of social separation models of depression. After numerous studies demonstrated the pathological effects of prolonged separation (weeks or months) of infant monkeys from their mothers, Hinde and colleagues reported enduring effects of brief separation (6 days) during infancy on subsequent behavioral development when tested at 12 and 24 months. Alterations were observed with respect to the separated monkeys' responses to novelty and their independent exploration of the immediate environment. Thus, even brief periods of maternal separation appeared capable of inducing enduring alterations in behavior. However, there is no convincing evidence that either the acute or the chronic effects of early separation in monkeys bear meaningful relationships to human depression.

In naturally occurring adverse social circumstances, such as falling in rank, monkeys can exhibit a prolonged withdrawal from social interaction and a suppression of aggression. Thus, some nonhuman primate analogs of the common precipitants of human depressive episodes can induce despairlike reactions and behavioral changes reminiscent of human depression, thus conferring a degree of face validity. In turn, these responses are strongly influenced by

genes (species differences), early social experience, social support networks, and other physical aspects of environment. Also, these despair responses are associated with physiological changes such as alterations in sleep architecture, phenomena that frequently accompany depressive episodes in humans.

Mindful of the value of predictive validity in an animal model of depression, the effects of psychotropic drugs have also been tested in separated monkeys. Several groups have reported an attenuation of behavioral disruption following maternal and peer separation with chronic chemical antidepressant treatment. However, the pharmacological specificity of these effects is questionable because chlorpromazine (an antipsychotic drug with weak, if any, clinical antidepressant activity), alcohol, and diazepam have each been reported to have similar effects, depending on the dose administered and actual measures recorded. However, repeated electroconvulsive stimulation, an analog of the highly effective antidepressant treatment electroconvulsive therapy (ECT), has also been shown to have an antidespair profile of effects.

Nonprimate models Recent work suggests that manipulation of the early social environment of the rat and other rodents may represent useful depression models. Repeated neonatal maternal separation in the rat leads to a robust impairment of the control of behavior by primary and conditioned reward in adulthood, with reduced responses to environmental novelty, psychostimulant drugs, and changes in reward magnitude. Some of these early experience-induced changes may model the hedonic changes found in human depression. To date, the only studies of the effects of antidepressant drugs on long-term consequences of maternal separation have examined their effects on measures of HPA function and ethanol consumption.

Psychosocial stress paradigms have been used successfully in naturally territorial nonprimate species such as the tree shrew. If adults males are kept in visual and olfactory contact in the laboratory after a period of conflict, a stable dominant–subordinate relationship develops and the subordinate exhibits sleep disturbance, reduced grooming behavior, neuroendocrine changes reminiscent of those seen in some depressed patients, and both structural and functional changes to the hippocampal formation. Some of these effects can be ameliorated by treatment with a tricyclic antidepressant or with the atypical agent tianeptine. Social defeat procedures have also been used in rodents, but it is less clear whether they consistently produce any changes in reward-related behavior.

Conclusion

Depression models fulfill many different purposes and can be evaluated according to different criteria. They have contributed to our understanding of the neural basis of reward and how stress affects brain function. Hypotheses generated in the clinical have stimulated model design and information from models has informed clinical practice. The inherent difficulties in attempting to construct valid animal models of human depression are largely offset by the potential utility of the approach. Depression models offer the opportunity to control and manipulate variables that epidemiological and clinical research suggests may be influential, for example, genotype; early social experience; and magnitude, type, and duration of environmental stressors. Cautious interpretation of model data can advance our understanding of a complex and devastating mental disorder.

Glossary

<i>Cytokine</i>	A soluble protein that is produced by lymphocytes, monocytes, and macrophages, as well as by tissue cells and cells of the central nervous system; cytokines are released from a cell to influence the activity of other cells by binding a specific receptor and activating cell function.
<i>Immune system</i>	A variety of interactive cells and soluble molecules that provide for the body's defense against invading external pathogens; the immune system is composed of two components: humoral or antibody responses and cell-mediated responses.
<i>Inflammation</i>	A immune response that occurs to rid the body of an infectious agent or to remove and repair damaged tissue.
<i>Major depressive disorder</i>	A disorder characterized by a period of at least 2 weeks of depressed mood or loss of interest in nearly all activities with the presence of at least four other symptoms drawn from a list that includes

changes in appetite or weight, sleep, or activity; decreased energy; feelings of worthlessness or guilt; difficulty thinking or concentrating; and recurrent thoughts of death or suicidal ideation.

A research field that investigates the physiological systems that integrate behavioral and immunological responses and examines the interactions between the nervous system and the immune system in the relationship between behavior and health.

Psychoneuroimmunology

Introduction

Many immunological changes reliably occur in patients with major depressive disorder, as recently described in comprehensive meta-analyses of over 180 studies with more than 40 immune measures. This article provides a brief overview of the immune system and the pathways that mediate connections between the central nervous system (CNS) and the immune system. A detailed review of the various immune findings that occur in major depression is presented with consideration of the behavioral correlates and biological mechanisms that might contribute to immune changes in major depression. Finally, the clinical implications of immune alterations in depression for infectious disease risk and inflammatory disorders are addressed.

Immune System

The immune system is the body's defense against invading external pathogens such as viruses and bacteria and from abnormal internal cells such as tumors. Innate immunity refers to the body's resistance to pathogens that operates in a nonspecific way without recognition of the different nature of various pathogens, whereas specific immunity is acquired in response to the identification of non-self molecules called antigens. Macrophages and granulocytes are

examples of nonspecific immune cells that react to tissue damage by consuming debris and invading organisms. Natural killer (NK) cells are another example of nonspecific immunity that acts to kill virally infected cells in a nonspecific way without need for prior exposure or recognition. In contrast, each T cell or B cell is genetically programmed to attack a specific target by secreting antibodies (B cell) or by killing cells of the body that harbor a virus (T cell). Both innate and specific immunity are orchestrated by the release of interleukins or cytokines from immune cells; cytokines are protein messengers that regulate the immune cells. This cytokine network aids in the differentiation of the immune response and in the coordination of its magnitude and duration. For example, there are two main classes of cytokines secreted by the T cells. One class of cytokines, T helper type 1 (Th1) cytokines, supports T cell responses (e.g., the ability of T cells to kill virally infected cells), whereas another class of cytokines, T helper type 2 (Th2), supports an antibody-mediated humoral immune response. However, these immunoregulatory processes cannot be fully understood without taking into account the organism and the internal and external milieu in which innate and specific immune responses occur.

Figure 1 Hypothesized mediators of the effects of major depression on immunity and infectious disease risk in humans.

Biological Connections between the CNS and Immune System

Autonomic Nervous System

The CNS and the immune system are linked by two major physiological pathways: the hypothalamic-pituitary-adrenal (HPA) axis and the autonomic nervous system, composed of sympathetic and parasympathetic branches. The sympathetic nervous system (SNS) is a network of nerve cells running from the brain stem down the spinal cord and out into the body to contact a wide variety of organs, including the eyes, heart, lungs, stomach and intestines, joints, and skin. In organs where the immune system cells develop and respond to pathogens (e.g., bone marrow, thymus, spleen, and lymph nodes), sympathetic nerve terminals make contact with immune cells. Thus, sympathetic release of norepinephrine and neuropeptide Y, together with receptor binding of these neurotransmitters by immune cells, serve as the signal in this hard-wire connection between the brain and the immune system. In addition, sympathetic nerves penetrate into the adrenal gland and cause the release of epinephrine into the bloodstream, which circulates to immune cells as another sympathetic regulatory signal.

Many immune system cells change their behavior in the presence of neurotransmitters. Under both laboratory and naturalistic conditions, sympathetic activation has been shown to suppress the activity of diverse populations of immune cells including NK cells and T lymphocytes. In contrast, other aspects of the immune response can be enhanced. For example, catecholamines can increase the production of antibodies by B cells and the ability of macrophages to release cytokines and thereby signal the presence of a pathogen. Additional studies indicate that sympathetic activation can also shunt some immune system cells out of circulating blood and into the lymphoid organs (e.g., spleen, lymph nodes, thymus) while recruiting other types of immune cell into circulation (e.g., NK cells). In general, SNS activation can reduce the immune system's ability to destroy pathogens that live inside cells (e.g., viruses) via decreases of the cellular immune response, while sparing or enhancing the humoral immune response to pathogens that live outside cells (e.g., bacteria). Together, these observations are a cornerstone for understanding fundamental, neuroanatomic signaling between the autonomic nervous and immune systems.

Neuroendocrine Axis

The other way in which the brain can communicate with the immune system is the HPA system. This

process begins in the hypothalamus, an area of the brain that governs basic bodily processes such as temperature, thirst, and hunger. Following the release of neuroendocrine factors from the brain, the endocrine glands secrete hormones into the circulation, which reach various organs and bind to hormone receptors on the organs. Under conditions of psychological or physical stress, for example, the hypothalamus increases its release of corticotropin-releasing hormone (CRH) into a small network of blood vessels that descends into the pituitary gland. In response to CRH, the pituitary gland synthesizes adrenocorticotrophic hormone (ACTH), which travels through the bloodstream down to the adrenal glands and triggers the release of a steroid hormone called cortisol from the outer portion of the adrenal glands. Cortisol exerts diverse effects on a wide variety of physiological systems and also coordinates the actions of various cells involved in an immune response by altering the production of cytokines or immune messengers. Similar to sympathetic catecholamines and neuropeptide Y, cortisol can suppress the cellular immune response critical to defending the body against viral infections. Indeed, a synthetic analog of cortisol is often used to suppress excessive immune system responses (e.g., in autoimmune diseases such as arthritis or in allergic reactions such as the rash produced by poison oak). Cortisol can also prompt some immune cells to move out from circulating blood into lymphoid organs or peripheral tissues such as the skin. What is even more remarkable about the interactions between the neuroendocrine and immune system is that immune cells can also produce neuroendocrine peptides (e.g., endorphin, ACTH), which suggests that the brain, neuroendocrine axis, and immune system use the same molecular signals to communicate with each other.

Central Modulation of Immunity

Together, this converging evidence of brain-immune system interactions legitimizes the possibility that the brain has a physiological role in the regulation of immunity. Indeed, one key peptide involved in integrating neural and neuroendocrine control of visceral processes is CRH. Release of this peptide in the brain alters a variety of immune processes, including aspects of innate immunity, cellular immunity, and *in vivo* measures of antibody production. Relevant to immune alterations in depression, CRH is elevated in the cerebrospinal fluid of depressed patients. Hence, the brain through the endogenous release of CRH controls immune cells in lymphoid tissue in the same manner it controls other visceral organs, namely, by coordinating autonomic and neuroendocrine pathways; when these

pathways are blocked by specific factors that bind to sympathetic or hormone receptors, the effects of CRH or brain stimulation on immune function are also blocked.

Depression Influences on Immunity

Enumerative Measures

Evidence for increases in the total number of white blood cells and in the numbers and percentages of neutrophils and lymphocytes was among the first immunological changes identified in depressed persons. Further evaluation of lymphocyte numbers in depression has used phenotype-specific cell surface markers to enumerate lymphocyte subsets and found that depression is negatively related to the number and percentage of lymphocytes (B cells, T cells, T helper cells, and T suppressor/cytotoxic cells) as well as the NK cell phenotype.

Functional Measures

For the evaluation of the function of the immune system in depressed patients, a majority of studies have relied on results from assays of nonspecific mitogen-induced lymphocyte proliferation, mitogen-stimulated cytokine production, and NK cytotoxicity. More than a dozen studies have been conducted on lymphocyte proliferation in depression, and there is a reliable association between depression and lower proliferative responses to the three nonspecific mitogens, including phytohemagglutinin (PHA), concanavalin-A (Con A), and pokeweed (PWM). In addition, a number of independent laboratories have confirmed the finding of reduced NK activity in major depression.

Stimulated Cytokine Production

Studies of stimulated cytokine production have not yielded consistent findings. For example, increased lipopolysaccharide stimulated production of interleukin-1 β (IL-1 β) and IL-6 in depressed patients, but resulted in no change in the expression of another pro-inflammatory cytokine, tumor necrosis factor α (TNF- α). There are also reports of a shift in the relative balance of Th1 vs. Th2 cytokine production with increases in the capacity of lymphocytes to produce interferon in depression. However, no difference in the stimulated production of IL-2 has been found. These negative findings cannot be ascribed to differences in depressed samples, as depressed patients who show declines in NK activity show no difference in IL-2 production.

Inflammation and Circulating Levels of Inflammatory Markers

The presence of immune activation in major depression has also been evaluated by examining circulating levels of inflammatory markers, as well as Th1 cytokines; one study reported increases of plasma levels of IL-12 in a large cohort of depressed patients. Meta-analyses indicate that depression is associated with an increase in circulating levels of the pro-inflammatory cytokine IL-6. It is hypothesized that increases in circulating levels of pro-inflammatory cytokines are due to activation of monocyte populations, and increases in circulating levels of other pro-inflammatory cytokines such as TNF- α and IL-1 β have also been reported in depressed patients. Additional studies have extended these observations and assayed markers of systemic inflammation such as acute phase proteins and/or levels of soluble interleukin-2 receptor (sIL-2R), although findings are mixed. Nevertheless, increases in C-reactive protein have been found in association with depression with elevated levels in healthy depressed adults, as well as in those depressed patients with acute coronary syndrome. In turn, systemic immune activation is thought to lead to endothelial activation in depression with increases in the expression of soluble intercellular adhesion molecule.

Dissociation between Declines of Innate Immunity and Inflammatory Markers

Little attention has been given to the potential relationship between measures of innate immunity, such as NK activity, and levels of inflammatory markers in the context of major depression. In a recent study, levels of NK activity, circulating levels of IL-6, sIL-2R, and acute phase proteins were measured in patients with current major depressive disorder. Whereas patients with major depressive disorder showed lower NK activity and higher circulating levels of IL-6, levels of NK activity were not correlated with IL-6 or with other markers of immune activation including acute phase proteins or sIL-2R. Such findings have implications for understanding individual differences in the adverse health effects of major depressive disorder. Some depressed persons show reductions of cellular and innate immune responses that are associated with infectious disease susceptibility, whereas other studies report that depression is linked to immune activation that is associated with risk of inflammatory disorders such as rheumatoid arthritis and cardiovascular disease.

Viral-Specific Immune Measures

Extension of these nonspecific measures of immunity to viral-specific immune response has suggested a

functional decline in memory T cells that respond to at least one virus, namely, the varicella zoster virus, which is thought to be a surrogate marker for herpes zoster risk. Psychological stress is also associated with decline in specific immune responses to immunization against viral infections, although extension of this work to major depression has not yet been conducted.

Assays of *in Vivo* Responses

Basic observations in animals have raised the possibility that depression can alter *in vivo* immune responses, as administration of chronic stress suppresses the delayed type hypersensitivity (DTH) response. Translation of these findings suggests that suppression of the DTH response to a panel of antigenic challenges occurs in depression.

Clinical Moderating Variables

Heterogeneity in the effects of depression on immunity can be accounted for by a number of factors such as age, gender, ethnicity, adiposity, and health behaviors (e.g., smoking, alcohol consumption). Older adults show declines in cellular immunity, and the presence of comorbid depression appears to magnify further age-related immune alterations. Gender of the subject exerts differential effects on pituitary-adrenal and immune systems by modulating the sensitivity of target tissues, and women undergoing laboratory stress show exaggerated expression of cytokines that lead to inflammation as compared to men. Such inflammatory responses to stress may place depressed women at increased risk for autoimmune disorders. In contrast, declines of T cell and NK cell response appear to be more prominent in depressed men than in depressed women. Regarding ethnicity, African American ethnicity interacts with a history of alcohol consumption to exacerbate immune abnormalities, but the effects of ethnicity on depression-related immune alterations are not known. Increases in body mass index and the presence of obesity are associated with increases in markers of inflammation such as circulating levels of C-reactive protein and IL-6. It has been suggested that adiposity and greater body mass partially mediate the increase of inflammatory markers in depression, although other data indicate that elevated levels of inflammatory markers may occur only above a threshold of adiposity or in those with obesity. Finally, depressed patients who are comorbid for alcohol abuse or tobacco smoking show exaggerated declines of NK activity.

Behavioral Mechanisms: Role of Insomnia

Insomnia is one of the most common complaints of depressed subjects, with potential mediating effects on immune alterations in depression. Disordered sleep and loss of sleep are thought to adversely affect resistance to infectious disease, increase cancer risk, and alter inflammatory disease progression. Recent epidemiological data show that self-reported difficulty initiating sleep is a predictor of cardiovascular disease mortality, and objective measures of difficulty initiating sleep (i.e., prolonged sleep latency) yield a twofold elevated risk of death in a healthy older adult population. Animal studies further show that sleep deprivation impairs influenza viral clearance and increases rates of bacteremia, with translational data showing that acute sleep loss reduces immune response to immunization against influenza and hepatitis B.

In humans, normal sleep is associated with a redistribution of circulating lymphocyte subsets, increases of NK activity, increases of certain cytokines (e.g., IL-2, IL-6), and a relative shift toward Th1 cytokine expression that is independent of circadian processes. Conversely, sleep deprivation suppresses NK activity and IL-2 production, although prolonged sleep loss has been found to enhance measures of innate immunity and pro-inflammatory cytokine expression.

In depressed patients, subjective insomnia correlates with NK activity in depression, but not with other depressive symptoms. Recent studies in bereaved persons show that insomnia mediates the relationship between severe life stress and a decline of NK responses. Furthermore, in patients with primary insomnia, prolonged sleep latency and fragmentation of sleep are associated with nocturnal elevations of sympathetic catecholamines and declines in daytime levels of NK cell responses, similar to the abnormalities found in depression. Finally, EEG sleep measures in depressed patients showed that prolonged sleep latency and increases of REM density correlated with elevated levels of IL-6 and sICAM and fully accounted for the association between depression and IL-6.

Depression Treatment: Effects of Antidepressant Medications

Only a limited number of studies have investigated the clinical course of depression and changes of immunity in relation to antidepressant medication treatment and symptom resolution. In a longitudinal case-control study, depressed patients showed increases in NK activity during a 6-month course of

tricyclic antidepressant medication treatment, although improvements in NK activity correlated with declines in symptom severity and not medication treatment status at the follow-up. However, both *in vivo* and *in vitro* treatment with fluoxetine, a selective serotonin reuptake inhibitor, results in enhanced NK activity along with changes in depressive symptoms, consistent with the effects of a number of other selective serotonin reuptake inhibitors on NK responses. Other studies have focused on pro-inflammatory cytokine expression and inflammation and concluded that antidepressants decrease pro-inflammatory cytokine (e.g., IL-1 β , TNF- α , and IL-6) and induce a shift toward Th2 cytokine expression. However, such alterations in the production of cytokines appear to be confined to medication responders, suggesting that symptom resolution is a relatively more important predictor of the cytokine changes than antidepressant medication status.

Cytokines Influences on the CNS and Behavior: Implications for Depression

Not only does the brain participate in the regulation of immune responses, but also the CNS receives information from the periphery that an immune response is occurring with consequent changes in both electrical and neurochemical activity of the brain. During immunization to a novel protein antigen, the firing rate of neurons within the brain (e.g., ventromedial hypothalamus) increases at the time of peak production of antibody; this part of the brain controls autonomic activity. Cytokines released by immune cells are increasingly implicated as messengers in this bidirectional interaction, and the release of IL-1 following activation of macrophages with virus or other stimuli induces alterations of brain activity and changes in the metabolism of central brain chemicals and neurotransmitters such as norepinephrine, serotonin, and dopamine in discrete brain areas. Much recent data have focused on how these cytokines signal the brain given their large molecular size and inability to cross readily the blood-brain barrier. It is now known that IL-1 and possibly other inflammatory cytokines communicate with the brain by stimulating peripheral nerves such as the vagus that provide information to the brain. In sum, the immune system acts in many ways like a sensory organ, conveying information to the brain, which ultimately regulates neuroendocrine and autonomic outflow and the course of the immune response.

Immune activation also leads to changes of peripheral physiology and behaviors that are similar to a stress response. With peripheral immune activation, pro-inflammatory cytokines are expressed in the

CNS, CRH is released by the hypothalamus, and there is an induction of a pituitary adrenal response and autonomic activity. Coincident with these physiological changes, animals show reductions in activity, exploration of novel objects, social interactions, food and water intake, and a willingness to engage in sexual behaviors. Taken together, this pattern of behavioral changes (i.e., sickness behaviors) is similar to that found in animals exposed to fear or anxiety-arousing stimuli and can be reproduced by the central or peripheral administration of IL-1. In contrast, central administration of factors that block IL-1 antagonizes these effects. These cytokine-brain processes are also implicated in increased sensitivity to pain stimuli that is found following nerve or tissue injury.

Translation of these data to clinical samples suggest that physiological activation of the immune system by bacterial products with the release of pro-inflammatory cytokines leads to increases of depressed mood and anxiety, and decreases of verbal and non-verbal memory function. Moreover, large doses of cytokines, given as immunotherapy for cancer or hepatitis C commonly induce depression-like symptoms such as depressed mood, inability to experience pleasure, fatigue, poor concentration, and disordered sleep, which can be effectively treated by giving antidepressant medications. Cytokines can also alter sleep in humans. Expression of the Th2 or anti-inflammatory cytokine IL-10 prior to sleep predicts amounts of delta sleep during the nocturnal period, whereas levels of pro-inflammatory cytokine IL-6 are associated with declines of delta sleep and increases of REM sleep. Likewise, pro-inflammatory cytokine activation is implicated in daytime fatigue, with links identified in cancer survivors as well as healthy older adults.

Clinical Implications of Psychoneuroimmunology

The factors that account for individual differences in the rate and severity of disease progression are not fully understood, although increasing evidence suggests that behavioral and multisystem physiological changes that occur during depression or stress come together to exacerbate the course of many chronic diseases. In the following sections, several pertinent diseases examples are discussed.

Cardiovascular Disease

Atherosclerosis is now thought to be an inflammatory process that involves a series of steps, each of which appears to be impacted by depression. Activated macrophages within the vascular space secrete

pro-inflammatory cytokines, which in turn leads to expression of adhesion molecules. With recruitment of immune cells to the vascular cell wall or endothelium and the release of inflammatory cytokines, the vascular endothelium expresses adhesion molecules that facilitate further binding of immune cells. Importantly, psychological and physical stressors increase both release of pro-inflammatory cytokines and expression of adhesion molecules that tether (slow down) and bind immune cells to the vascular endothelium. Moreover, it appears that depression is associated with activation of the endothelium. Acute coronary patients who are depressed show an increased expression of an adhesion molecule that is released following activation of the vascular endothelium (i.e., soluble intracellular adhesion molecule). Importantly, this molecular marker of endothelial activation, as well as IL-6, predicts risk of future myocardial infarction, independent of cholesterol levels, smoking status, and obesity. In prospective studies, both depressed mood and inflammatory markers contribute independently to the risk for coronary heart disease, particularly in men.

HIV

HIV infection shows a highly variable course, and depression, bereavement, and maladaptive coping responses to stress (including the stress of HIV infection itself) have all been shown to predict the rate of immune system decay in HIV patients. For example, major depression in women with HIV infection was associated with lower NK activity, as well as increases in the numbers of activated CD8 lymphocytes and viral load, which suggested that declines of killer lymphocytes in association with depression may increase risk of HIV disease progression in women. Immune system decline and HIV replication are particularly rapid in patients living under chronic stress (e.g., gay men who conceal their homosexuality by living in the closet) and in patients with high levels of SNS activity (e.g., socially inhibited introverts). Tissue culture studies have shown that SNS neurotransmitters and glucocorticoids can accelerate HIV replication by rendering T lymphocytes more vulnerable to infection and by suppressing production of the antiviral cytokines that help cells limit viral replication.

Depression and Rheumatoid Arthritis: Neuroimmune Mechanisms

In a negative feedback loop, pro-inflammatory cytokines stimulate the HPA axis that results in the secretion of glucocorticoids, which in turn suppresses the immune response. However, in autoimmune

disorders such as rheumatoid arthritis, it is thought that the counterregulatory glucocorticoid response is not fully achieved. In animals that are susceptible to arthritis, there is a central hypothalamic defect in the biosynthesis of CRH, blunted induction of ACTH and adrenal steroids, and decreased adrenal steroid receptor activation in immune target tissues that together contribute to weak HPA response, one that is not sufficient to suppress the progression of an autoimmune response. Rheumatoid arthritis patients also show a relative hypofunctioning of the HPA axis despite the degree of inflammation. Stress and depression can lead to HPA axis activation and to increases of pro-inflammatory cytokines, and recent data suggest that stressful events, particularly those of an interpersonal nature, provoke symptoms of disease such as greater pain and functional limitations. Moreover, the presence of depression in rheumatoid arthritis patients undergoing stress is associated with exaggerated increases of IL-6, a biomarker predictive of disease progression. Conversely, administration of a psychological intervention that decreases emotional distress produced improvements in clinician-rated disease activity in rheumatoid arthritis patients, although immunological mediators were not measured. Likewise, in the case of another autoimmune disorder, psoriasis, a stress reduction intervention, mindfulness meditation, was found to induce a more rapid clearing of the psoriatic lesions.

Cancer

Experimental studies conducted in animal models have shown that exposure to acute stress leads to decreases in NK cell function and facilitates the metastatic spread of NK-sensitive tumors. However, translation of these data has been challenging; clinical findings supporting a link between depression and cancer have been mixed, with limited evidence to support the contribution of immune mechanisms. Immunogenic tumors have rarely been investigated in the context of depression and psychoneuroimmunology. In addition, other physiological systems, such as the endocrine system, may also play a role; for example, dysregulated cortisol rhythm is associated with both reduced NK activity and increased mortality in metastatic breast cancer patients. Behavioral interventions in the setting of cancer recovery appear to impact disease outcomes such as recurrence and survival. In metastatic breast cancer patients, group psychotherapy led to improvements in mood and increased survival time, controlling for initial staging and medical care during the follow-up period. Among patients with malignant melanoma, group psychotherapy was

associated with decreases in distress, increases in active coping, and increases in NK cytotoxicity, as well as a higher rate of survival. Both baseline NK cytotoxicity and improvements in coping behavior were associated with disease outcomes in this study.

Overview of Stress and Dermatology

Role of Stress over the Life Cycle

The Role of Stress in a Wide Range of Dermatological Symptoms

Stress and Some Specific Dermatological Disorders

Glossary

Alopecia areata An immunologically mediated disorder that results in hair loss; it may present in three degrees of severity: (1) single or multiple patches of well-demarcated hair loss, often on the scalp; (2) total or near total loss of scalp hair (termed alopecia totalis); and (3) generalized loss of body hair (termed alopecia universalis). Alopecia areata may occur at any age; the

Atopic dermatitis

peak incidence is during the third to fifth decades.

A chronically relapsing disorder, marked by periods of exacerbations and remission, characterized by a rash manifesting from patches of red irritated skin and raised papules to areas where the skin is thickened, with accentuation of the skin markings, usually due to repeated scratching. In any one individual, the skin lesions can vary; itching is a central feature of the disorder and some patients may present with dry scaly skin. It appears in early infancy, childhood, and adolescence, frequently associated with elevated serum immunoglobulin E levels and a family history of atopic dermatitis, allergic rhinitis, and asthma; also called atopic eczema.

Hyperhidrosis

An increased, above normal sweat production.

Pruritus

Itching; this symptom is the predominant feature of inflammatory skin diseases; however, it may be a symptom of a wide range of disorders, from dry skin

	to an occult cancer. Repeated scratching and rubbing can lead to thickening of the skin with accentuated skin markings and a clinical entity known as lichen simplex chronicus.
<i>Psoriasis</i>	A chronic relapsing disorder characterized by skin lesions of variable appearance. The skin lesions often present as raised circular plaques with redness and scales on the elbows, knees, and the scalp behind the ears; however, the lesions may be generalized and affect the entire body or may be localized to just the palms and soles. Pitting of the nails is often associated with psoriasis. Itching and the shedding of the skin scales are some of the most bothersome symptoms.
<i>Rosacea</i>	A chronic disorder of the face, often the nose, characterized by redness and superficial blood vessels, with or without papules. It is a disorder of adults, usually between ages 30 and 50 years. The onset of rosacea is insidious.
<i>Urticaria</i>	Hives that present as circumscribed, typically itchy, red evanescent areas of swelling. The individual lesions arrive suddenly and rarely persist for longer than 48 h; however, they may continue to recur for indefinite periods. Immunological factors such as allergies play a central role in acute urticaria; however, in the majority of cases of chronic urticaria (i.e., when the lesions are present beyond 6–8 weeks) the underlying cause is not determined.

Overview of Stress and Dermatology

Psychosocial stress has long been recognized as being associated with the onset and/or exacerbation of a wide range of dermatological disorders. Most of the literature on stress and skin disease refers to atopic dermatitis or atopic eczema and psoriasis. The term stress has been used to address three major areas in dermatology: (1) major stressful life events such as the death of a loved one, divorce, or loss of livelihood; (2) stress resulting from the social stigma associated with a cosmetically disfiguring skin disorder such as psoriasis or interpersonal stress resulting from having to provide care to someone with a chronic and recurring disorder such as childhood eczema, which in turn may have an adverse impact on the course of a stress-reactive skin disorder; and (3) traumatic life events that represent situations that overwhelm the coping capacity of the individual – unlike commonly experienced situations (such as simple bereavement),

traumatic events such as maternal neglect, severe emotional abuse, and sexual abuse generally are events that are outside the range of normal human experience and are significantly distressing to almost everyone.

Stress may influence dermatological symptoms in three major situations: (1) in primary stress-reactive skin disorders, such as psoriasis, atopic dermatitis or eczema, urticaria, acne, and alopecia areata, in which neuroendocrine and psychoneuroimmunological factors are believed to play an important role; (2) in disorders that represent an accentuated physiological response such as hyperhidrosis (or excessive perspiration) and blushing; and (3) in skin disorders, such as dermatitis artefacta, neurotic excoriations, or trichotillomania, that are secondary to an underlying psychiatric condition such as obsessive-compulsive disorder, posttraumatic stress disorder, or major depressive disorder. Nutritional deficiencies encountered in eating disorders such as anorexia nervosa and sometimes bulimia nervosa can result in diffuse hair loss or alopecia. Stress exacerbates the dermatological symptoms by aggravating the underlying psychiatric disorder.

Various neurobiological factors have been implicated in stress-mediated skin disorders. Stress-induced analgesia is observed in animals faced with inescapable stressors. Fear activates the secretion of endogenous opioid peptides, and this effect is blocked by naloxone in animal models. This may be a factor in itching, scratching and self-injury that occur during extremely stressful situations.

Psychosocial stress has been associated with the activation of the hypothalamic-pituitary-adrenocortical (HPA) axis and the sympathetic and adrenomedullary (SAM) system. Stressful emotional experiences disturb the regulation of the HPA and the SAM systems; that is, in the face of stress, physiological systems may operate at higher levels, resulting in higher glucocorticoid levels, or lower levels than normal. Recent studies have shown that psychological stress, such as examination-related stress, is associated with derangements in the epidermal (most superficial layer of the skin) permeability barrier function and that the alterations were proportional to the severity of the stressor. It has been proposed that this is mediated by increased endogenous glucocorticoids. Both psoriasis and atopic dermatitis demonstrate increased transepidermal water loss and deterioration of barrier function. Higher anxiety levels in acne patients have been associated with high blood catecholamine levels, which decreased with the treatment of the acne, suggesting that the anxiety in acne is associated with significant physiological stress for the patient and activation of the SAM system.

It has further been observed that there is increased responsiveness of the HPA axis in response to a heel prick stressor in newborns with a family history of atopy or elevated levels of cord blood immunoglobulin E (IgE). Patients with atopic dermatitis also show elevated eosinophil counts and elevated IgE expression in response to stress. Atopic patients with serum IgE levels greater than 100 IU ml^{-1} demonstrated significantly higher levels of excitability and less adequate coping with stress than did patients with lower IgE levels. IgE is considered to be important in atopic dermatitis because it mediates hypersensitivity reactions by stimulating mast cells and basophils.

Chronic stress may induce a state of hyporesponsiveness of the HPA axis whereby glucocorticoid secretion is decreased, leading to an increased secretion of mediators of inflammation such as the cytokines, which are normally regulated by cortisol. Animal data show that a blunted responsiveness of the HPA axis to stress is closely linked to an increased susceptibility to inflammatory disease. Stress-induced hyporesponsiveness of the HPA system has also been proposed to be a factor in some chronic inflammatory dermatoses such as atopic dermatitis.

Role of Stress over the Life Cycle

The interface between psychosocial stress and dermatological disorders begins early in the life cycle and persists throughout adult life because of the role of the skin as a vital organ of communication. The role of stress in dermatological disorders therefore has to be assessed from a developmental perspective. The skin plays an integral role as an organ of communication right from birth because the skin is the primary organ of attachment. The newborn infant's initial physical experience is largely tactile, and the child requires secure holding and hugging to develop physically, neurologically and psychosocially. Psychosocial stressors, such as maternal deprivation, neglect, or abuse during early life and the lack of adequate tactile nurturance in institutions such as orphanages, can impact a child's entire body, and the sequelae of such types of stressors are often manifested in a wide range of dermatological symptoms. Spitz observed that the lack of a nurturing mother-child relationship in an institutional setting was associated with the development of certain syndromes such as rocking, fecal play, and infantile eczema. In this institutionalized population, 15% of the infants had infantile eczema compared with a 2–3% prevalence in the general population. A child's need to be held and physically nurtured may be neglected in cases in which he or she has a severe skin disease; alternatively a child's chronic recurring skin disorder

may place inordinate stress on the caregiver and affect his or her capacity to nurture the child. In some instances, this interpersonal stress may in turn have an adverse impact on stress-reactive skin conditions such as eczema in a vicious cycle.

The onset of a cosmetically disfiguring skin disorder during adolescence often renders the patient very vulnerable to stress because he or she is also dealing with emerging hormonal and physical changes of puberty, body-image issues, and dealing with other developmental tasks of adolescence such as peer pressure, dating, and career choice. Adolescence is also associated with a high incidence of mood disorders such as major depressive disorder. The peak incidence of acne is during adolescence. In addition to the rise in the level of androgens that is the primary trigger for acne, the psychosocial stresses of this life stage can also contribute to flare-ups of the acne. Therefore, psychosocial stress may contribute to flare-up of acne and the acne in turn may result in significant stress for the patient. It is important to recognize that the adolescent patient may be especially vulnerable and may react to even relatively minor acne with a serious psychiatric disorder such as major depression and suicidal ideation. Alternatively, there have been incidences of violent acting out by adolescents who were having difficulty coping with the psychosocial, particularly peer-related, stresses associated with disfiguring acne. In young adulthood and later life, the emergence of stress-reactive disorders such as psoriasis may have a significant impact on the patient's social and occupational functioning, and the stress resulting from the stigmatization may in turn cause flare-ups of the psoriasis.

The Role of Stress in a Wide Range of Dermatological Symptoms

Some general stress-related factors may play a role in a wide range of skin disorders.

Pruritus or Itching

Pruritus is a feature of a wide range of skin disorders to varying degrees, including the common disorders that are exacerbated by psychological stress such as psoriasis, atopic dermatitis, and urticaria. Pruritus has been reported to be exacerbated by stress in up to 86% of cases in large surveys. Stress may also increase scratching behavior, which in turn can trigger the itch-scratch cycle and, in some instances, cause further flare-ups of the underlying skin condition, such as atopic dermatitis. Pruritus may further be a source of significant distress for the patient; it is often rated as the most bothersome feature of the skin disorder and has been associated with suicide.

Stress-induced scratching and itching may lead to the development of conditions such as lichen simplex chronicus, in which the superficial layer of the skin thickens as a result of repetitive scratching.

Disease-Related Stress

The impact of a skin disorder on quality of life, especially due to the cosmetic disfigurement and social stigma that are typically associated with a wide range of skin disorders, can be a source of significant stress for the patient. In some chronic stress-reactive dermatoses such as psoriasis and atopic dermatitis, this disease-related stress may in turn cause the underlying skin condition to flare up and may become an important confounding factor.

Stress-Related Self-Injury/Manipulation of the Skin

When faced with stressful situations, patients may pick at minor irregularities or existing lesions in their skin, scratch themselves excessively, or pluck their hair. Injury to the skin may exacerbate a primary skin condition such as psoriasis secondary to the Koebner phenomenon or may cause flare-ups of acne as a result of the underlying inflammatory process.

The skin is frequently the focus of tension-reducing behaviors, both because of its easy access and because of the primary role of the skin in early attachment. Attachment-related trauma occurs when there is abuse or neglect in early life, and this is often associated with self-injury to the body, especially the skin. Posttraumatic stress disorder (PTSD) associated with a history of sexual, physical, and/or emotional abuse results in a dysregulation of internal emotional states. The PTSD patients may excessively manipulate their skin or hair in an attempt to regulate their affect. The tension-reducing behavior and self-injury may manifest as the self-induced dermatological conditions such as neurotic excoriations, dermatitis artefacta, neurodermatitis, and trichotillomania. In cases in which high levels of stress and dissociation are present, patients may not even recall self-inducing their lesions as a result of dissociative amnesia and may be mistaken as malingers.

Stress and Some Specific Dermatological Disorders

Acne

Emotionally stressful events such as examinations are known to exacerbate acne; furthermore, increasing stress has been shown to be correlated with an increase in acne severity. The stress resulting from the impact of acne on the quality of life of the patient

is comparable to chronic disorders such as diabetes and asthma, and it often does not correlate with the clinical severity of acne – even mild acne may be associated with significant stress.

Acne excoriee is a condition that results from repetitive picking and excoriation of the acne lesions. A stress-related syndrome that is often underrecognized in acne excoriee is PTSD, usually secondary to abuse and/or neglect during early life; patients with PTSD often injure themselves, and this can manifest as recurrent acne excoriee. In some of these patients, the problems caused by the recurrent self-excoriation are more problematic than the primary acne lesions that were excoriated. Some PTSD patients dissociate when excoriating themselves and may not have full recollection of the times when they excoriated their acne lesions.

Alopecia Areata

Psychosocial stress has been reported to play a role in the onset and exacerbation of alopecia areata; however, this association is less robust. Various studies indicate a lack of a direct relationship between stress and the severity of alopecia areata, suggesting stress may be a factor that just triggers the onset of the disease process. One study reported mental stress within 3 months before the onset of alopecia areata by 23% of 114 patients surveyed, and an additional 22% reported suffering from stress that was not related to the appearance of the alopecia. In one study of 52 patients, all patients reported “a very unhappy or stressful life,” whereas in another study only 6.7% of 178 patients reported a severely disturbing event 6 months before the onset of symptoms. One study reported that patients whose alopecia areata is stress-reactive may suffer from depressive illness.

Atopic Dermatitis or Atopic Eczema

Stressful life events may precede the onset of atopic dermatitis or eczema in up to 70% of cases. Itching is a central feature of atopic dermatitis. Disease-related stress, interpersonal stress, and stress resulting from the family environment are important predictors of symptom severity in atopic dermatitis. Atopic patients have been shown to scratch more readily in response to an itch stimulus, suggesting that they develop a conditioned scratch response more readily than controls. Perceived itch may be enhanced in atopic patients in response to mental stress. The scratching can trigger the itch-scratch cycle, which can become a problem in cases of nocturnal itching and scratching. Some earlier studies reported high psychophysiological reactivity in atopic patients; however, this has not been supported by more recent studies that

carried out psychophysiological measures such as blood pressure, heart rate, and skin conductance.

Hyperhidrosis or Excessive Perspiration

Hyperhidrosis has been associated with stress in up to 100% of cases. Over 25% of patients with social phobia or social anxiety disorder, in which the patients experience heightened stress and physiological arousal in social situations, report hyperhidrosis to be a significantly distressing symptom.

Psoriasis

Various studies have reported an association between stress and psoriasis. A study that retrospectively examined the role of stress in the onset of a wide range of skin conditions reported that patients with psoriasis were more likely to report that a stressful experience predated the onset and exacerbation of their condition than patients with other skin diseases. In a study of 132 psoriasis patients, 39% recalled a significant stressful life event (e.g., interpersonal stress within the family, death or hospitalization of close relatives, accidents, sexual assault, and examinations) within 1 month before the first episode of psoriasis, in contrast to 10% of patients with conditions that are generally not associated with stress. A stressful life event was reported 1 month before the onset of psoriasis in 72% of 179 patients with psoriasis. In a survey of 245 children with psoriasis, stress was observed to be a provocative factor among 90% of the children. The severity of the stressor does not typically correlate with the time to onset or the exacerbation of psoriasis, possibly because of considerable individual variation in coping skills and the importance of the emotional meaning rather than the absolute intensity of the life event. PTSD has been associated with a long-term impact on physical health and a wide range of disorders affecting the immune system, including psoriasis. A recent study of 2490 Vietnam war veterans reported an adjusted odds ratio of 4.7 (95%, CI 1.9–11.7) for psoriasis among veterans with comorbid PTSD. The autonomic dysregulation associated with PTSD may be an underlying perpetuating factor in patients with recurring or treatment-resistant psoriasis.

Rosacea

Factors such as overwhelming life stress, an anxious and immature personality associated with excessive feelings of guilt and shame, and social anxiety secondary to easy blushing have all been implicated in rosacea. Psychological stress has been

implicated as a factor among 20–94% of patients with rosacea.

Urticaria

Increased mental tension and fatigue have been spontaneously reported as the main exacerbating or precipitating factors by 77% of 43 patients. Out of 100 patients with chronic urticaria and/or angioedema, 51% reported that stressful life situations were associated with the onset of symptoms, compared with 8% of surgical controls. Earthquakes and other catastrophic life events have been associated with the onset of urticaria. There have been case reports of patients with PTSD secondary to severe physical abuse, who developed linear urticarial lesions in the same region of the body where they had experienced the beatings in their early life.

Desensitization of the Stress Response
Cellular Mechanisms of Desensitization

Glossary

<i>Heterotrimeric G proteins</i>	A group of proteins that consist of three subunits (α , β , γ) and couple cell surface receptors to their effector enzymes. On activation of cell surface receptors by their ligands, heterotrimeric G proteins dissociate into the α subunit and the β - γ complex, both of which regulate the activity of effector enzymes in the cell membrane.
<i>Neuroendocrine motoneurons</i>	Hypothalamic nerve cells that produce and secrete neurohormones into the hypophyseal portal circulation and thus regulate the synthesis and release of anterior pituitary hormones.
<i>Protein kinases</i>	Enzymes that tag proteins with phosphoryl residues derived from ATP. The activity of protein kinases may be regulated by a variety of intracellular messengers, protein-protein interactions, or phosphorylation by other protein kinases.

Desensitization is a widespread phenomenon in biological systems whereby the response to persistent or invariant stimuli is reduced.

Desensitization of the Stress Response

As if to react selectively to new or stronger stimuli, biological systems diminish their responses to persistent or stable stimuli in a process termed desensitization, adaptation, or habituation. The stress response is no exception to this rule. A reduction in the activation of the hypothalamic-pituitary-adrenocortical (HPA) axis and behavioral arousal elicited by the same and repeatedly applied stressor occurs in most cases. This is called homotypic desensitization. The degree and speed of desensitization may depend on the frequency and the length of exposure to the

stressor as well as on the genetic make-up of the experimental subjects. Heterotypic desensitization, a blunting of the response to several types of stress induced by repeated exposure to a single stressor, is less common but has been observed. More frequently, the application of a heterotypic stressor in subjects that have undergone homotypic desensitization elicits an exaggerated HPA response to the heterotypic stimulus when compared with nondesensitized controls. This indicates that homotypic desensitization affects the stressor-specific mechanisms of the HPA response as well as the final common pathways of neuroendocrine regulation. Indeed, chronic stressors are known to increase the expression of vasopressin dramatically in the neuroendocrine motoneurons of the hypothalamic paraventricular nucleus, whereas the expression of corticotropin releasing hormone (CRH) remains essentially unchanged. This is likely to augment the pituitary response to stimuli that impinge on the neuroendocrine motoneurons and may well explain the enhanced pituitary adrenocorticotropin response to heterotypic stressors in subjects with homotypic desensitization.

A general attenuation of the HPA response to several stressors occurs in lactating animals. This has been attributed to the suppression of the HPA axis at the level of the paraventricular nucleus by oxytocin. By contrast, stressor-specific habituation does not take place at the level of the paraventricular neuroendocrine motoneurons.

Cellular Mechanisms of Desensitization

At the cellular level, desensitization manifests itself in biological processes as diverse as bacterial chemotaxis and mammalian neurotransmission. Desensitization affects signal-transduction pathways by which cells detect and decode changes in the extracellular milieu. The molecular and cellular details of desensitization are particularly well explored with respect to seven-transmembrane domain receptors (7-TMRs) coupled to heterotrimeric G-proteins. Significantly, plasma membrane receptors for CRH, vasopressin, and catecholamines are in this category.

On binding their respective agonist ligands, receptors activate heterotrimeric G-proteins, which leads to the stimulation of various intracellular effector enzymes that generate intracellular second-messenger molecules. Within a few seconds, cells can diminish or virtually eliminate their agonist-evoked responses through a process that involves the phosphorylation

of the 7-TMRs on one or more intracellular domains. The cellular response to a given agonist may be desensitized by cellular exposure to that agonist itself in a process called homologous desensitization. Alternatively, the desensitization of the response to a given agonist may be caused by agonists for distinct receptor signaling systems in a process termed heterologous desensitization. Potentially affecting multiple receptor systems, heterologous desensitization involves the phosphorylation of 7-TMRs by second-messenger-dependent kinases, such as cAMP-dependent protein kinase and protein kinase C (PKC). In most cells, a further elaborate system exists to trap activated 7-TMRs – the G-protein-coupled receptor kinases and arrestins. These are distinct and independent of second-messenger-stimulated kinases; further, they are specific for activated 7-TMRs and are involved in homologous desensitization.

The common feature of all of these mechanisms is the phosphorylation of 7-TMRs and their consequent uncoupling from G-proteins. Interestingly, uncoupling from G-proteins in many cases leads to the activation of alternative signaling pathways for these receptors involving arrestins as the coupling proteins. Thus, although one aspect of receptor action (e.g., the generation of cAMP) may be desensitized, signaling through another pathway (e.g., the stimulation of microtubule-activated protein kinase) may be turned on. The receptors tagged by phosphorylation may be endocytosed and recycled on dephosphorylation or eventually degraded, depending on the requirements of the cell.

Even longer-term control of signal transduction pathways may involve the alteration of the transcription of receptor genes or their effector systems,

potentially entirely reprofiling the cellular response as a result of prolonged exposure to receptor ligands.

Introduction

Increased Central Nervous System Driving of the
Hypothalamic-Pituitary-Adrenal Axis
Cushing's Syndrome

Glossary

<i>Adrenal cortex</i>	The outer layer of the adrenal glands, which secretes several steroid hormones, including glucocorticoids, mineralocorticoids, and adrenal androgens. The adrenal glands lie just above the kidneys.
<i>Adrenal androgens</i>	Hormones produced by the adrenal cortex that have weak male sex hormone-like effects.
<i>Aldosterone</i>	The principal mineralocorticoid produced by the adrenal cortex in humans.
<i>Amygdala</i>	A group of nerve cells in the temporal lobes of the brain that stimulates the secretion of corticotropin-releasing hormone and, in turn, the rest of the hypothalamic-pituitary-adrenal cortical axis.
<i>Corticotropin (adrenocorticotrophic hormone, ACTH)</i>	A hormone produced by cells in the anterior pituitary gland that is carried by the bloodstream to the adrenal cortex, where it stimulates the secretion of glucocorticoids, mineralocorticoids, and adrenal androgens.
<i>Corticotropin-releasing hormone (CRH)</i>	A hormone produced by neuroendocrine cells of the hypothalamus that is transported down the pituitary stalk to the anterior pituitary gland, where it stimulates the secretion of ACTH.
<i>Cortisol (hydrocortisone)</i>	The principal glucocorticoid produced by the adrenal cortex in humans. Under normal circumstances, cortisol feeds back to the pituitary gland, hypothalamus, and other brain areas to reduce the secretion of CRH and ACTH, thereby reducing the secretion of cortisol and other adrenal cortical hormones.
<i>Dexamethasone</i>	A synthetic glucocorticoid having 25 times the potency of cortisol.
<i>Glucocorticoids</i>	Hormones produced by the adrenal cortex that increase glucose production in the liver, increase glucose utilization

by tissues, inhibit glycogen formation by body tissues, and promote lipid breakdown in fat tissue. The principal glucocorticoid in humans is cortisol. When administered in high therapeutic doses or when present in excess due to overproduction by the adrenal glands, glucocorticoids suppress immunological function, reduce inflammation, and decrease connective tissue and new bone formation.

A group of nerve cells in the temporal lobes of the brain that inhibits the secretion of CRH and, in turn, the rest of the hypothalamic-pituitary-adrenal cortical axis.

A hormone axis consisting of cells in the hypothalamus of the brain that secrete CRH and vasopressin (AVP), which stimulate the secretion of ACTH from the anterior pituitary gland into the bloodstream. In turn, ACTH stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids, and adrenal androgens into the bloodstream.

The area at the base of the brain that controls vital body processes including the production of hormones that stimulate and inhibit the secretion of anterior pituitary hormones.

Hormones produced by the adrenal cortex that reduce the excretion of sodium and enhance the excretion of potassium and hydrogen ions by the kidney. The principal mineralocorticoid in humans is aldosterone.

A gland, connected to the base of the brain by the pituitary stalk, that secretes several hormones into the bloodstream that stimulate the adrenal cortex, the thyroid gland, the gonads (testes and ovaries), and other tissues of the body.

A hormone produced by cells in the hypothalamus that is transported down the pituitary stalk to (1) the anterior pituitary gland, where, along with CRH, it stimulates the secretion of ACTH, and (2) the posterior pituitary gland, from which it is carried by the bloodstream to the kidneys, where it reduces the excretion of water.

Hippocampus

Hypothalamic-pituitary-adrenal cortical (HPA) axis

Hypothalamus

Mineralocorticoids

Pituitary

Vasopressin (AVP; antidiuretic hormone, ADH)

Introduction

The HPA axis is regulated by two processes. One is the closed-loop negative feedback of cortisol to hormone receptors in the hippocampus, hypothalamus, and pituitary gland. This suppresses the secretion of CRH, ACTH, and cortisol itself. This process is

analogous to control of heat by a thermostat; at a certain temperature, the heat signals the thermostat to shut down the heater until the temperature drops, then the heater goes on again, and the cycle repeats itself. The second process is the open-loop driving of the HPA axis by the central nervous system (CNS). Areas of the brain, including the amygdala, hippocampus, and hypothalamus, stimulate and inhibit the HPA axis to different degrees depending on the time of day, season of the year, and physical and environmental stressors.

The HPA axis has a circadian (24-h) rhythm. The secretion of CRH, ACTH, and adrenal hormones is greatest at 7–8 a.m., an hour or so after awakening, and at its lowest about 2–3 a.m. The difference in blood concentrations of ACTH and adrenal glucocorticoids such as cortisol is approximately fourfold between the nadir (low point) and the peak several hours later. If a person shifts his or her sleep–wake cycle, it takes approximately 2 weeks for the HPA axis to resynchronize its circadian rhythm.

The HPA axis is very stress-responsive. Both physical and psychological stressors can cause increased activity of this hormone axis. In particular, novel stressors (stressors that are new experiences) cause HPA axis activation; with a person's repeated encountering of the stressor, there is less and less HPA axis response. This is particularly true of demanding tasks, which initially provoke an HPA axis response but do not after the person achieves mastery of the task through training and experience. This change is called neuroendocrine adaptation.

Pathological (abnormal) function of the HPA axis can occur from several causes. These include repeated uncontrollable environmental stressors; functional psychiatric illnesses such as major depression and schizophrenia; and disorders of the HPA axis itself, such as hormone-secreting tumors of the pituitary gland and adrenal cortex. The dexamethasone suppression test (DST) is one of several endocrine tests that can help diagnose the particular pathological process resulting in abnormal HPA axis activity.

Increased Central Nervous System Driving of the Hypothalamic-Pituitary-Adrenal Axis

As mentioned, repeated, uncontrollable environmental stressors, functional psychiatric illnesses such as major depression and schizophrenia, and other conditions can increase CNS stimulation of the HPA axis to such a degree that it is relatively insensitive to dexamethasone suppression. Major depression is the best-studied psychiatric illness in this regard; 30–50% of major depressives have mildly to moderately increased HPA axis activity, consisting of

increased blood concentrations of ACTH and cortisol at all times of the day and night, with preservation of the circadian rhythm of these hormones. Correlated with this increase is nonsuppression of ACTH and cortisol on the low-dose DST. In the low-dose DST, 1–2 mg of dexamethasone is given orally at 11–12 p.m., and blood samples are taken at 8, 16, and 24 h thereafter for measurement of circulating cortisol concentrations. Normally, cortisol is suppressed to low levels (less than 50 ng ml⁻¹) for a full 24 h. Depressed patients with increased HPA axis activity often show early cortisol (and ACTH) escape from dexamethasone suppression. That is, there may be early suppression of these hormones the morning (8 h) following dexamethasone administration, but hormone concentrations are prematurely increased in the 16- and/or 24-h blood samples. The rapidity and degree of cortisol escape in the DST is an indication of the strength of CNS driving of the HPA axis. It also may be a good indication of recovery from major depression.

Depressed patients who have an initially abnormal DST, who are treated with antidepressant medication, and who have both a good clinical response and a reversion of their DST to normal are more likely to remain in remission when their medication is discontinued. On the other hand, patients who have an apparently good clinical response but who persist with an abnormal DST are more likely to experience relapse, even when continuing antidepressant treatment. In some patients with recurrent depressive episodes, the DST may become abnormal again before clinical symptoms emerge, signaling that a relapse may be imminent and allowing the physician to reinstitute treatment at the earliest possible time. This finding of a neuroendocrine change preceding any clinical change has been well documented in patients with rapidly cycling bipolar disorder. They generally have normal DST suppression of cortisol when manic, but dexamethasone resistance appears up to a week before they switch to the next depressive phase. In patients with mixed bipolar episodes, when both manic and depressive features coexist, the DST is usually abnormal. Because of its change with clinical status, the DST is considered a state marker rather than a trait marker of major depression.

Major depression is a heterogeneous disorder that includes patients with a wide range of clinical profiles (see **Depression and Manic-Depressive Illness**). Abnormal DST results are seen most commonly in those with melancholic depression, psychotic depression, and mixed bipolar episodes. Advancing age and global severity, especially incapacitation, are other important correlates of abnormal DST results in depression. Abnormal DSTs have been reported in depressed prepubertal children and in depressed and bipolar adolescent inpatients. Abnormalities are seen least often in young patients with milder depressions,

especially when these are of short duration and are precipitated by adverse life events. In uncomplicated bereavement and adjustment disorder with depressed mood, the DST is normal.

When used in patients with a well-established diagnosis of major depression, an abnormal DST signifies that the patient is very likely to benefit from somatic treatment such as antidepressant medication and electroconvulsive therapy. In controlled clinical trials of antidepressant drugs in heterogeneous depressed populations, the rates of response to placebo and active drug when the DST is abnormal are approximately 10 and 70%, respectively. In patients with normal DST results, the corresponding response rates are 55 and 65%, respectively. Thus, the drug-attributable, specific response rates are 60% in patients with an abnormal DST and 10% in patients with a normal DST. When cognitive psychotherapy has been used to treat depressed inpatients who have abnormal DSTs and/or elevated urinary free cortisol excretion, without concomitant use of antidepressant drugs, only 44% responded, compared with 92% of patients whose HPA axis biomarkers were normal. Other, long-term follow-up studies have found that depressed patients with abnormal DST results, in comparison to those with normal test results, have an eightfold risk of switch from unipolar major depression to bipolar disorder, an eightfold risk of completed suicide, and an eightfold risk of rehospitalization. Severely depressed patients who require ECT have a very high rate of positive DST results.

When used as a diagnostic test, the DST has several problems. Even for melancholic depression, test sensitivity or true positive rate is only approximately 50%. This means that a negative test result does not rule out the diagnosis. The specificity of the test, or true negative rate, varies with the populations studied. When careful exclusions were applied for medical and drug confounds, specificity of 90% or greater was found in early reports. With wider use, however, lower specificity has been observed. The most common reasons in practice for false-positive DST results are certain drugs, especially anticonvulsant agents that accelerate the metabolism of dexamethasone; conditions marked by notable weight loss, such as anorexia nervosa or cachexia associated with cancer; Alzheimer disease, possibly due to loss of hippocampal inhibitory control on the HPA axis; and the marked physiological stress associated with acute, uncontrolled psychosis. Thus, in accordance with Bayesian principles, the predictive value of a positive DST as a confirmatory test is high when there is strong suspicion of major depressive illness in a given patient, as determined by clinical examination and other tests, but the predictive value is considerably reduced when the DST is incorrectly used as a screening test for major depression (that is, when

there is a low base rate of the illness in a given population).

A final problem, which is largely responsible for the present clinical disuse of the DST, is that it is now agreed that measurement of plasma dexamethasone concentrations is required for a valid interpretation of DST results. When low doses of dexamethasone (1–2 mg) are used, with sampling times up to 24 h later, the plasma dexamethasone concentrations achieved in normal subjects are just above the threshold needed to suppress the HPA axis. Any factor that accelerates the rate of clearance of dexamethasone from plasma therefore will be associated with false-positive results. Low plasma dexamethasone concentrations may be caused by genetic variability of drug clearance or by the factors previously listed that are associated with reduced test specificity. This becomes of particular concern when very low doses of dexamethasone (0.25–0.5 mg) have been used to attempt to enhance the sensitivity of the test.

It also should be mentioned that underactivity of the HPA axis, along with enhanced suppression of ACTH and cortisol by dexamethasone, has been noted in patients with posttraumatic stress disorder (PTSD), such as in holocaust survivors, combat veterans, and resulting from childhood sexual abuse. The reason for reduced, rather than increased, HPA axis activity in the face of repeated psychological reexperiencing of traumatic incident(s), as occurs in PTSD, has been hypothesized to be related to enhanced CNS glucocorticoid receptor feedback sensitivity. For example, patients with PTSD have been described as being supersensitive to very low dexamethasone doses.

Cushing's Syndrome

Cushing's syndrome is the group of clinical signs and symptoms resulting from increased circulating glucocorticoids of long duration. There are many clinical changes in Cushing's patients, including obesity of the face and trunk, weakness and atrophy of limb muscles, increased blood pressure, imbalance of glucose metabolism, and psychological changes. There are two main types of Cushing's syndrome, ACTH-dependent and ACTH-independent. ACTH-dependent Cushing's syndrome results from increased pituitary secretion of ACTH, usually from a pituitary tumor (Cushing's disease); inappropriate ACTH secretion by nonpituitary tumors, often in the lungs; and inappropriate CRH secretion by nonhypothalamic tumors, in turn stimulating excessive pituitary ACTH secretion. These conditions, all involving excess ACTH production, cause enlargement of the adrenal glands and excessive cortisol secretion. ACTH-independent Cushing's syndrome is caused by primary tumors or abnormalities of the adrenal cortex itself, resulting in excessive cortisol secretion and suppression of ACTH production by the

pituitary. Prolonged administration of glucocorticoids for the treatment of certain illnesses also may cause ACTH-independent Cushing's syndrome.

The DST is one of several endocrine tests used to diagnose the different causes of Cushing's syndrome. Indeed, the DST was originally developed to aid endocrinologists in the differential diagnosis of hypercortisolemic and Cushingoid states. In the differential diagnosis of Cushing's syndrome, dexamethasone is administered in different dosage strengths and for different periods of time in a series of low- and high-dose tests. The route of administration may be oral or intravenous. The relative resistance of ACTH and cortisol to dexamethasone suppression is noted, along with baseline circulating ACTH and cortisol concentrations and their response to stimulation by administered CRH. The excessive pituitary production of ACTH and adrenal production of cortisol in Cushing's disease are only partially suppressible by low-dose dexamethasone but are more suppressible by higher doses. In contrast, patients with nonpituitary sources of ACTH production will rarely show suppression of ACTH and cortisol by dexamethasone. Similarly, patients with ACTH-independent Cushing's syndrome will not show suppression of cortisol, even with high doses of dexamethasone, because their ACTH already is suppressed by the independently high circulating cortisol concentrations and dexamethasone does not act to suppress the adrenal cortex directly.

It should be emphasized that, in diagnosing the causes of Cushing's syndrome, the DST must be interpreted in the light of other endocrine findings. For example, one important distinction between the increased ACTH and cortisol production in some patients with major depression versus patients with Cushing's disease is that the former have preservation of their circadian rhythms of ACTH and cortisol, whereas the latter often have high circulating hormone concentrations throughout the entire 24 h. Major depressives also do not have the clinical changes seen in Cushing's syndrome, because their body tissues are not exposed to equivalent, continuously high circulating cortisol concentrations. The mean 24-h plasma cortisol concentration in Cushing's disease exceeds 250 ng ml⁻¹, whereas in psychotic depression it is around 100–120 ng ml⁻¹ and in normal subjects around 60–80 ng ml⁻¹. The differences in tissue exposure to free cortisol are even greater, because the cortisol-binding transport protein in plasma, transcortin, is reduced in Cushing disease but normal in depression. The DST therefore must be considered as just one in a series of clinical examinations and laboratory studies used to determine the causes of increased HPA axis activity.

DEX/CRH Test in Depressive Disorders and Other
Psychiatric Diseases

Conclusion

Glossary

<i>Adrenal cortex</i>	Part of the adrenal gland secreting different steroid hormones such as glucocorticoids, mineralocorticoids, and androgens after stimulation with releasing hormones from the pituitary gland.
<i>Adrenocorticotropic hormone (ACTH)</i>	A hormone secreted from the anterior pituitary gland that induces glucocorticoid secretion from the adrenal cortex.
<i>Corticotropin-releasing hormone (CRH)</i>	A neuropeptide hormone mainly secreted by the paraventricular nucleus of the hypothalamus. One main effect is the induction of ACTH secretion at the level of the anterior pituitary gland. Additionally, CRH is well known to be involved in anxious and depressive mood and behavior.
<i>Dexamethasone (DEX)</i>	A synthetic glucocorticoid with a 25 times higher binding affinity to glucocorticoid receptors of the pituitary than cortisol itself. Since DEX is not able to cross the blood–brain barrier, the negative-feedback sensitivity of the HPA system can be assessed at the level of the pituitary gland.
<i>Glucocorticoid receptor (GR)</i>	This receptor type is widely distributed in the central nervous system, such as the hypothalamus, the limbic system, including the hippocampus, and the cortex. In concert with the hippocampal MR, it is mainly involved in the negative

Glucocorticoids

Hypothalamic-pituitary-adrenal (HPA) axis

Mineralocorticoid receptor (MR)

Vasopressin

feedback regulation in case of stimulated HPA-activity. During unstimulated conditions only 5–10 percent of central GRs are occupied by the ligand.

Steroid hormones, secreted by the adrenal cortex, with cortisol as the principle human glucocorticoid. Their main effects are induction of liver glucose production, inhibition of glucose metabolism in body tissues and lipid decomposition in fat tissue. In higher concentrations, glucocorticoids results in suppression of immunological function with anti-inflammatory effects. Cortisol, which readily crosses the blood–brain barrier serves as a negative-feedback signal on hypothalamic CRH and vasopressin as well as pituitary ACTH secretion.

A hormone system encompassing the hypothalamus that secretes the neuropeptides CRH and vasopressin and which in turn stimulates the anterior pituitary to release ACTH. This pro-opiomelanocortin-derived hormone then induces glucocorticoid, e.g., cortisol, release at the level of the adrenal cortex. The HPA system constitutes a long-loop, negative-feedback system, with cortisol and ACTH inhibiting further ACTH and CRH release via hippocampal glucocorticoid and mineralocorticoid receptor occupancy. Activation of the HPA system occurs mainly via afferents from the brain stem and cortical areas.

Centrally, this receptor type is only found in the CA-3 layer of the hippocampus. There it is mainly co-localized with glucocorticoid receptors and regulates HPA-system activity. Hippocampal MRs bind GRs with a 6–10-fold higher affinity than GRs and are almost completely occupied by the ligand under resting conditions, whereas the GR is only occupied at times of stress activation and/or the circadian peaks of the HPA system.

A neuropeptide hormone that regulates in concert with CRH HPA system drive. Vasopressin- and CRH-expressing neurons are to a large part co-localized in the paraventricular nucleus.

* This DEX/CRH test should be distinguished from the endocrine DEX/CRH test employed in the differential diagnosis of patients with Cushing syndrome from those with Pseudo-Cushing syndrome, i.e., obese patients with hypercortisolism due to psychological factors or chronic active alcoholism that cannot be differentiated otherwise. This test entails administration of a higher dose of dexamethasone (0.5 mg 4 times a day for 2 days prior to the administration of CRH). Presence of an ACTH and cortisol response to CRH denotes Cushing syndrome.

Introduction

To study the functioning of the hypothalamic-pituitary-adrenal (HPA) system in humans there are

four possible options: (1) assessing basal, circadian secretory profiles; (2) using psychological stressors, such as free speech in front of an audience; (3) using physical stressors, e.g.; treadmill exercise; or (4) applying pharmacological challenge tests. Psychological stressors activate the HPA system by stimulating the limbic and cortical areas (prefrontal cortex (PFC), hippocampus, amygdala), and the paraventricular nucleus (PVN) of the hypothalamus. A more direct pathway for the PVN to secrete CRH is reached by both physical stressors and pharmacological challenges. The dexamethasone (DEX)-suppression test, the CRH test, and the combined DEX/CRH test act at the level of the pituitary and indirectly, at the adrenal level and allow the assessment of feedback sensitivity of the HPA system.

A low dose of dexamethasone (1.5 mg), a synthetic glucocorticoid with a high binding affinity to glucocorticoid receptors of the pituitary, given in the late evening results in a suppression of ACTH- and subsequently cortisol release the following day in healthy, unstressed subjects. In depressed patients or stressed individuals, however, low-dose dexamethasone is insufficient to suppress ACTH and cortisol adequately, a phenomenon known as escape from DEX-suppression or DST-nonsuppression. By administering a physiological dose of CRH to healthy, unstressed humans, the pituitary responds with markedly increased ACTH secretion, whereas in depressed patients and in stressed individuals who are hypercortisolemic, the same test will result in a blunting of ACTH release and no measurable changes in prechallenge cortisol concentrations. The reason for this outcome is due to the fact that the higher basal cortisol levels in these subjects feedback negatively to the pituitary, putting a brake on ACTH release after CRH. When exposed to the combined DST plus CRH test (DEX/CRH test) depressed patients frequently show excessive, and not blunted, hormonal (ACTH and cortisol) responses, indicating that both CRH and vasopressin drive HPA-system activity. This conclusion is indirectly derived from the following observations: first, in depression and in experimental animals under chronic stress conditions a shift to a gradually intensifying vasopressinergic regulation of the pituitary-adrenocortical system occurs. Second, the low dose of DEX used in the DEX/CRH test acts primarily on the pituitary and thereby suppresses ACTH and cortisol. In the brain, however, the depletion of endogenous cortisol is not compensated by low-dose DEX since it is unable to cross the blood-brain barrier. Third, as a result, in a depressed DEX-pretreated patient, secretion of ACTH in response to exogenous CRH is greater than in healthy control subjects because of the synergistic actions of the

administered CRH bolus with a large amount of vasopressin present at the corticotrophs. This notion is supported by findings in experimental animals where excessive hormonal responses in the DEX/CRH test could be normalized by pretreatment with a vasopressin antagonist. Also, increased numbers of CRH- and vasopressin-expressing neurons in the PVN have been reported in postmortem studies of depressed patients.

Procedures

CRH test

In endocrine challenge procedures timing is of utmost importance since most hormonal systems have a circadian rhythm. In order to achieve measurable hormone responses and to avoid ceiling effects it is preferable to perform challenge tests at the lowest circadian hormone activity. Also, possible confounding factors need to be controlled.

The CRH stimulation test consists of an intravenous (IV) bolus injection of 100 µg human CRH (hCRH) or 1 µg kg⁻¹ ovine CRH (oCRH), reconstituted in 1 ml 0.02% hydrochloric acid in 0.9% saline, in the late afternoon or early evening when the HPA system is relatively quiescent. Subjects should rest in a supine, comfortable position in a single room after having had a light lunch at least 2 h prior to the procedure. An IV forearm catheter should be put in place 30 min before blood sampling starts to allow for adaptation. In most laboratories the catheter is then connected to a long tubing system which is passed through a sound-proof lock (through-the-wall-technique) into the adjacent laboratory where the blood sampling is performed. Between blood samplings the IV line is kept patent by saline infusion at a rate of 50 ml h⁻¹. Thirty minutes and immediately before bolus injection of CRH, blood samples for baseline levels of ACTH and cortisol are drawn. During the first 2 h after CRH administration blood should be sampled every 15 min, thereafter every 30 min for a further 1 h. In healthy controls, ACTH peak responses occur after 15–30 min while cortisol peaks about 30–60 min after CRH administration. CRH stimulation results in at least a twofold ACTH response with a fairly high interindividual variance and the cortisol response is usually greater than 270 nmol l⁻¹. However, in subjects with hypothalamic dysfunctions (e.g., depression) hormonal responses to CRH may be augmented with delayed peaks. In cases where higher doses of CRH are used, a biphasic ACTH response can be observed caused by cortisol feedback effects. Also, due to a longer half-life, oCRH has a prolonged effect on the pituitary.

Side effects of CRH are normally very mild and transient and may include heat flashes in the area of thorax, neck, or face, thoracic constriction, shortness of breath, and/or quickening of breathing and heart rate.

DEX/CRH Test

Subjects receive 1.5 mg dexamethasone orally at 23.00 p.m. The following day, after a light lunch around 12.00 p.m. they are fitted with an IV forearm catheter at 14.30 p.m. (same procedure as described above for the CRH test). The first blood sample is drawn at 15.00 p.m. (postDEX, but preCRH – referred to as basal). At 15.05 p.m. CRH is injected, and thereafter blood is sampled every 15 minutes until 16.15 p.m.

Results in the DEX/CRH tests are usually reported as hormone concentrations at the predetermined time points. In addition, two derivative parameters, the DELTA-value (peak concentration after 15.05 p.m. minus basal concentration at 15.00 p.m.) and the AUC value (area under the concentration time curve minus linear background, determined by the trapezoidal rule, arbitrary units).

Impact Factors

Factors that impact on the outcome of both the CRH test and the combined DEX/CRH test are manifold, but the most important in the context of stress and depression research are time of day, age, gender, phase of menstrual cycle, and medication. Obviously, any medical, especially endocrine disorder, can have major effects on the test results.

Age

Most DEX/CRH test studies found that elderly patients have higher DELTA and AUC of ACTH and cortisol values in comparison to those in young subjects. Together with the observation that baseline, resting cortisol levels – as assessed by repeated, circadian blood or saliva sampling – are elevated in older age, these findings suggest that the activity of the HPA system increases and feedback inhibition might decrease during aging. To date, it is still unclear and a matter of great debate, whether this increasing HPA-system activity in aging constitutes a physiological or adaptive response to the accumulation of daily hassles of life or whether this is an indication of gradually failing compensatory endocrine mechanisms.

Gender

Women, especially elderly women, release more ACTH and cortisol after DEX/CRH challenge than elderly men. Also, DEX-pretreated, basal hormone concentrations tend to be higher in women compared with men. However, this gender difference is not pronounced in younger (aged < 30 years) individuals. This age-gender interaction in DEX/CRH test outcome may be due in part to the larger reductions in gonadal steroids (estradiol) in older, postmenopausal women.

Menstrual-Cycle Phase

Menstrual-cycle phase as well as estrogen administration (e.g., oral contraceptive use or hormonal replacement therapy (HRT)) are consistently found to have a major impact on HPA reactivity. Women show a reduced HPA reactivity during the follicular phase of the menstrual cycle as opposed to the luteal phase. In elderly women who received HRT, ACTH and cortisol responses to DEX/CRH stimulation were dampened in comparison to placebo-treated elderly females. To the best of our knowledge, studies in men with regard to testosterone and challenge test outcomes are not yet available.

Medication

A variety of different drugs has been shown to alter HPA-system activity and thus, endocrine challenge-test results. Antidepressants but also benzodiazepines and antipsychotic drugs, for example, are known to alter HPA-system activity. Thus it is advisable to perform challenge tests in drug-free individuals, unless, the effect of certain medications are of interest. Note, that alcohol, caffeine, and nicotine increase HPA-system activity, and, unfortunately, withdrawal from these substances has the same effect!

DEX/CRH Test in Depressive Disorders and Other Psychiatric Diseases

The DEX/CRH test is one of the most sensitive neuroendocrine function tests to assess HPA dysregulation in psychiatric disorders, including dementia, exceeding greatly the sensitivity of the DST (at least in the case of major depression). However, it should be emphasized that DEX/CRH test results are non-specific, that is, they are not indicative for any mental syndrome.

Several studies used repeated DEX/CRH testing to monitor HPA system functioning during the course of antidepressant treatment. It was shown that initially abnormal HPA responses gradually disappeared in those patients responding favorably to treatment. Noteworthy is the fact that normalization of HPA-system functioning preceded the resolution of psychopathological symptoms. In contrast, patients whose HPA system imbalance did not sufficiently normalize during the course of treatment, had a greater liability for an early relapse.

With respect to bipolar disorder enhanced HPA reactivity after DEX/CRH challenge is also well known and is more pronounced compared to patients with unipolar depression. Furthermore, patients with remitted bipolar disorder have higher responses compared to those with unipolar remitted disorder and healthy controls.

To tackle the issue whether HPA dysregulation is a disease-predisposing, pre-existing vulnerability factor or whether it is a consequence of depression, high-risk, but healthy probands, with at least one depressed, first-degree relative underwent DEX/CRH testing. The high-risk probands, who themselves had never suffered from depression, showed higher cortisol responses compared with controls. However, HPA responses to DEX/CRH challenge in high-risk probands who developed an affective disorder during the 4-years follow-up period did not differ in terms of DEX/CRH results from those high-risk subjects who had remained healthy during this period. These findings suggest that subtle changes of HPA-system function are a genetic trait that increases the risk of developing depression and possibly other stress-related disorders.

An enhanced release of ACTH and cortisol following DEX/CRH compared with healthy controls is also described in other psychiatric disorders such as schizophrenia, panic disorder, and borderline-personality disorder, especially in case of early sexual or physical abuse.

Conclusion

In conclusion, HPA-system dysbalance is a frequent neuroendocrine sign in patients with mental disorders or in individuals subjected to stressful conditions. To assess activity of the HPA-system basal measurements of cortisol concentrations in saliva, blood, or 24-h urine may be used, each mode of collection having its specific advantages and disadvantages. To study HPA-system regulation, the DST has been the most widely used procedure since it is simple to apply,

relatively inexpensive, and benign for the individual. During the last decade, the combined DEX/CRH-stimulation test has gained increasing attention, mostly in research settings, due to its high sensitivity for stress-related conditions and mental disorders. With the emergence of the DEX/CRH test as a laboratory test in psychological and psychiatric research, the usage of the simple CRH test in this context has markedly declined. However, no single test is superior to any other, their applicability, reliability and validity depending solely on the research questions asked.

Glossary

<i>γ-Aminobutyric acid (GABA)</i>	A major transmitter in the brain; known to be implicated in anxiety.
<i>Addison's disease</i>	A condition resulting from the failure of the adrenal glands; treated by replacing the missing hormones.
<i>Adrenal cortex</i>	The outermost part of the adrenal gland, which secretes a variety of steroid hormones including cortisol and DHEA.
<i>Adrenarche</i>	A stage that occurs at around 8 years in humans; characterized by a rapid increase in DHEA levels in the blood.
<i>Adrenocorticotrophic hormone (ACTH)</i>	A hormone secreted by the pituitary gland that controls the activity of part of the adrenal cortex (e.g., cortisol secretion).
<i>Allosteric interaction</i>	The interaction of two molecules because of their shape.
<i>Androgen</i>	A set of steroids having masculine-like actions on the body; testosterone is the major one in humans.
<i>Anoxia</i>	The lack of oxygen.
<i>Blood-carrier (binding) protein</i>	A protein to which substances that are carried in the blood are bound; it affects the way they are transported into the brain and other tissues.

Cerebrospinal fluid (CSF)

The fluid surrounding the brain and also present inside it in cavities called ventricles; compounds entering or leaving the brain may travel through the CSF.

Downstream gene expression
Estrogens

The alteration of the way in which some genes are activated caused by steroids binding to DNA.

The major steroid hormones secreted by the ovaries and, during pregnancy, by the placenta.

Femoral neck

The upper part of the thigh bone that joins it to the pelvis; a common site of fracture in the elderly.

Glucocorticoids

One class of steroids secreted by the adrenals, including cortisol; so-named because, among other actions, they increase blood levels of glucose.

Hippocampus

An area of the brain associated with the formation of certain types of memory.

Immune function

The ability to resist infection; also associated with resistance to some forms of cancer.

Neurogenesis

The process of forming new nerve cells in the brain; occurs mostly during development but is now known to continue in some areas throughout adult life.

Neurosteroid

A steroid formed locally in the brain, as opposed to one synthesized and secreted by a peripheral endocrine gland. Some authors use the term to mean any steroid that has an action on the brain.

<i>Polycystic ovaries</i>	A largely inherited condition in which the ovaries contain large abnormal egg follicles; also associated with insulin resistance and obesity.
<i>Posttraumatic stress disorder (PTSD)</i>	A persistent disorder that sometimes follows the experiencing of life-threatening events or disasters; characterized by nightmares and persistent intrusive memories of the event, set off by a sight or sound associated with that event.
<i>Pregnenolone</i>	The first of a series of steroids made by the adrenal glands (and other organs) from cholesterol.
<i>Pyramidal neurons</i>	Large nerve cells found in several parts of the brain, including the hippocampus.
<i>Rodents</i>	A class of mammals that includes rats and mice.
<i>Serotonin (5-HT)</i>	A chemical used as a transmitter throughout the brain; implicated in depression and the target of a major class of antidepressants (the selective serotonin reuptake inhibitors, SSRIs).
<i>Toxins</i>	Substances that poison or damage cells.
<i>Ungulates</i>	A class of mammals that includes sheep and cows.

Dehydroepiandrosterone (DHEA) is an adrenal-derived steroid present in very high concentrations in the blood of primates. It is secreted mainly from the innermost zone of the adrenal cortex (the zona reticularis) which, in the human fetus, is hypertrophied and called the X zone. This reflects the fact that DHEA in the fetus is a major source of other steroids (e.g., estrogens). Because the human fetus itself lacks the enzymes to process DHEA, the formation of daughter steroids (e.g., estrogens and androgens) occurs in the placenta. At birth the X zone atrophies and blood DHEA falls to very low levels. Levels remain low until around age 8, when they begin to increase progressively, a process termed adrenarche. The stimulus that underlies adrenarche remains speculative (no pituitary controlling factor has so far been conclusively identified), as does its physiological significance, although DHEA can promote the growth of pubic hair. Levels continue to increase throughout puberty, reaching apogee in early adult life (around 20 years). In adulthood, DHEA is present in the blood largely (around 90%) as its sulfated derivative (DHEAS). There is about 10 times more DHEA(S) in the blood as cortisol, the next most abundant steroid. From its peak value, levels then decline progressively but variably with age, so that by around age 60 they are only approximately one-third or less of those during the twenties. As for

adrenarche, ignorance of the factors controlling the adrenal production of DHEA(S) prevents further understanding of the cause of this decline. Infusions of adrenocorticotrophic hormone (ACTH), the major controlling signal from the pituitary in the regulation of cortisol, also increase DHEA(S), but the very different life-span trajectory of DHEA compared to cortisol argues strongly against this being the only, or even the major, control system. For example, ACTH (and cortisol) do not increase during adrenarche, and levels of cortisol increase, if anything, with age. The functions of DHEA(S) in humans remain puzzling. Conversion to other steroids with known functions (e.g., estrogens and androgens) is quite small, and, in any case, seems unnecessary. Old World monkeys have a similar pattern of DHEA(S), but rats and ungulates have only very low levels (around 5% of those in humans) throughout the life span.

The rodent brain can make steroids locally from the precursor molecule cholesterol, including pregnenolone, the immediate precursor of DHEA. Such steroids are, consequently, called neurosteroids. However, it is uncertain whether the adult human brain (in contrast to the fetal one) has the enzymes required to convert pregnenolone into DHEA. In any case, the high amounts of DHEA(S) in the blood in humans seem to indicate that most DHEA(S) in the brain comes from the blood. Nevertheless, there are those who consider that local production of neurosteroids may play a significant role in regulating brain function, including mood and emotions. The direct measurement of DHEA and DHEAS in the cerebrospinal fluid (CSF), which gives a good indicator of the concentrations to which neurons are exposed, shows that DHEA levels are approximately 5% of those in the blood in humans and that DHEAS (a less lipid-soluble steroid) levels are approximately 0.2%. Levels in the saliva, a convenient way of measuring DHEA(S) status, are similar. In both cases, it is not clear what prevents more of the blood-borne steroid from entering the brain. No blood-binding proteins, which could limit the access of lipid-soluble steroids to the brain, have been identified for DHEA, yet the relative amounts in the blood and CSF correspond to other steroids (e.g., cortisol) that do have a blood-carrier (binding) protein. DHEA(S) levels in the blood are abnormally high in women with polycystic ovaries.

Stressful events, such as intercurrent illness, tend to lower DHEA(S) levels in humans (in contrast to cortisol, which is elevated). It is not clear how this relates to the age-dependent decline, that is, whether this occurs more or less in aged people or whether current (baseline) levels influence the response to

stress. People with lower baseline levels may be at increased risk for stress-related disorders such as coronary heart disease or major depression, although the literature is not unanimous on this. Interest in the DHEA response to stress lies in the possibility that it represent a resilience factor against some of the adverse results of chronic or intermittent stress. DHEA supplements are being taken by large numbers of older people as an anti-aging remedy – but mostly under unregulated circumstances, which prevents the accurate assessment of possible beneficial or adverse effects. Those with Addison's disease (adrenal failure) have virtually no DHEA in their blood, and restoring DHEA to near-normal values has beneficial effects on fatigue and, in some cases, mood. Supplementary DHEA in adrenal-intact older people has similar effects, but so far there have been no convincing reports of beneficial actions on cognitive functions such as memory. There is some evidence that age-related bone loss (e.g., in the femoral neck) may benefit from supplementary DHEA. There are no reports of people taking DHEA to counteract stressful events (such as a loss or excessive demand) or to prevent the adverse effects of life-threatening events (e.g., posttraumatic stress disorder, PTSD).

Experimental studies on DHEA have been mainly conducted on rodents, and it is important to remember that in these species DHEA administration is a pharmacological rather than physiological maneuver. Nevertheless, supplementary DHEA has been found to improve immune function (particularly in older animals). DHEA(S) may moderate the actions of glucocorticoids (cortisol in humans, corticosterone in rats), which may indicate a significant role for this steroid in stress-related responses in humans, in which cortisol levels can reach very high levels. Because excess cortisol has a variety of damaging actions on the body (including the immune system, metabolism, and brain function), individual or age-related differences in DHEA may influence the likelihood of adverse reactions to chronic or uncontrollable stress. DHEA counteracts the degeneration of the thymus that otherwise occurs after excess glucocorticoids (e.g., poststress) and has been found to improve survival rates after experimental infections in older mice. One of the measurable actions of glucocorticoids on the brain occurs in the hippocampus, an area that is curiously sensitive to the damaging actions of toxins and anoxia and that shows some of the earliest age-related changes in the brain, including those typical of incipient Alzheimer's disease. Corticosterone damages the pyramidal neurons in the CA3 region in rats and also reduces the proliferation

rates of progenitor (stem) cells in the dentate gyrus (part of the hippocampus), which continues to produce new neurons throughout adult life in rats and in humans. Neurogenesis declines with age; however, the functional significance of neurogenesis in the dentate gyrus (e.g., for certain forms of memory) is still uncertain. DHEA has some moderating actions on these glucocorticoid-dependent actions in the brain. It may also improve the survival of embryonic neurons and thus play a hitherto unsuspected role in neural development.

Depression is a well-known sequela to an acute stress (a severe adverse life event), and higher cortisol levels are a risk factor for subsequent depression. Cortisol is elevated during depression in some cases, and the cortisol/DHEA ratio has been shown to predict the persistence of or recovery from depression in adolescents (in whom DHEA is relatively high and rising). Recently, it has been proposed that altered neurogenesis in the hippocampus may underlie either the onset of depression or the ability of serotonin (5-HT)-acting drugs such as selective serotonin reuptake inhibitors (SSRIs) to alleviate this condition. If this is so, it points to another possible association between DHEA, which also has been shown to be an effective antidepressant in middle-age people, and the response to stress.

Understanding the way that DHEA has its effects is hampered by a lack of information about its actions at a cellular level. Unlike other steroids, no receptor in the interior of the cell has been identified for DHEA. This makes the way that DHEA alters cell function a mystery because these receptors are responsible for many of the effects of other steroids on cell function or downstream gene expression. Nor is the binding of corticosterone to its receptor altered by DHEA in rats, so there is no immediate explanation of the way that DHEA moderates glucocorticoids. In the brain, DHEA may interact allosterically with membrane-bound receptors for γ -aminobutyric acid (GABA_A) and this may go some way to explaining its actions on the central nervous system (CNS). What is clear is that defining DHEA(S) in humans as a weak androgen is not only inaccurate but has discouraged the investigation of the role of this prominent steroid in humans. Its unique age-related pattern of secretion and its possible role in intercurrent stressful events such as illness make such studies overdue.

Stress and Type 1 Diabetes Onset

Stress and Type 1 Diabetes Control

Stress Management Training and Type 1 Diabetes Control

Glossary

<i>B or β cells</i>	The cells in the islets of Langerhans in the pancreas that produce insulin.
<i>Diabetes mellitus</i>	A heterogeneous group of disorders, characterized by hyperglycemia, and disturbances of carbohydrate, fat, and protein metabolism that are associated with absolute or relative deficiencies of insulin secretion and/or insulin action.
<i>Glycosuria</i>	Sugar in the urine.
<i>Hyperglycemia</i>	Excessive levels of glucose in the blood; a feature of untreated or undertreated diabetes mellitus.
<i>Hypoglycemia</i>	Abnormally low levels of glucose in the blood. Symptoms are idiosyncratic but may include trembling, faintness, sweating, palpitations, mental confusion, slurred speech, headache, loss of memory, and double vision. Severe untreated hypoglycemia may lead to fits or coma and, on rare occasions, death. It can be caused by an overdose of insulin.
<i>Islet cell antibodies (ICAs)</i>	Antibodies that are present in the blood when the body develops an autoimmune reaction to the pancreatic islet cells. The presence of ICAs indicates that the process of destruction has started that will eventually lead to type 1 diabetes. This process appears to take several years before diabetes is clinically manifested.
<i>Insulin</i>	A peptide hormone produced in the β cells of the islets of Langerhans in the pancreas. Insulin facilitates and accelerates the movement of glucose and amino acids across cell membranes. It also controls the activity of certain enzymes within the cells concerned with carbohydrate, fat, and protein metabolism.

Type 1 diabetes mellitus, previously known as insulin-dependent diabetes mellitus (IDDM), juvenile-onset diabetes, or ketosis-prone diabetes, is the most common form of diabetes occurring in children and young adults of European origin. The age at clinical onset of the condition is usually under the age of 40 years and often under 30 years. People who have type 1 diabetes lose the ability to produce insulin. Exogenous insulin, usually delivered by injection, is needed continuously throughout the lifetime of a person with type 1 diabetes, with the possible exception of a brief honeymoon period that may occur within a year of clinical onset when endogenous insulin production is temporarily restarted. The onset of type 1 diabetes is abrupt, with severe thirst, excessive urination, and dramatic weight loss. Individuals usually present to the doctor with one or more of these symptoms and an elevated blood glucose level.

Once it has developed, type 1 diabetes can be managed by balancing a combination of insulin injections, intake of carbohydrates in the diet, and energy expenditure. The goal of treatment is to maintain blood glucose levels as close to the normal range as possible in order to reduce the risk of chronic complications while also avoiding the dangers of blood glucose falling to hypoglycemic levels.

Stress and Type 1 Diabetes Onset

Although it has not been possible to determine the exact pathogenesis involved in the expression of type 1 diabetes, it is clear that genetics play an important role. The genetic component of type 1 diabetes is indicated by its increased prevalence of 5% in first-degree relatives, compared with less than 1% in the general population. However, genetic susceptibility is not sufficient to cause diabetes because the majority of people with disease-associated alleles do not develop type 1 diabetes. Environmental factors play an important role in the overt expression of type 1 diabetes, although the mechanisms are still unclear. Psychological stress may have a role in increasing vulnerability to viral infection or impairing defense mechanisms against infection, thereby facilitating the progression of the hidden pathological process. For example, stress-related changes in immune function may increase the likelihood of viral or bacterial disease, which may provide the initial insult to the B (or β) cells. A second mechanism whereby stress may be implicated in diabetes onset may occur around the time when the diabetes becomes symptomatic.

Stress-related counterregulatory hormone activity may aggravate the metabolic disturbance that has already developed. In fact, if the already-elevated blood glucose level increases to beyond the renal threshold, glycosuria causes dehydration, which may then produce the first symptoms of overt diabetes. Many anecdotal accounts and descriptive reports of life stresses occurring synonymously with symptomatic type 1 diabetes onset may reflect this second mechanism in which stress triggers overt manifestation of symptoms.

Animal Studies

It has been shown that stress may be associated with the onset of type 1 diabetes in the genetic model for this type of diabetes. In the diabetes-prone BB Wistar rat, 30 to 70% of these animals have impaired glucose tolerance with hypoinsulinemia and hyperglycemia by 150 days of age. It has been shown that these rats developed diabetes earlier, when exposed to restraint and crowding. It has also been found in the BB rat that chronic stress significantly increases the incidence of the phenotypic expression of the gene for type 1 diabetes. It was found by Lehman et al. in 1991 that 80% of the stressed males and 70% of the stressed female animals developed diabetes, compared with 50% in both control groups. However, because of the range of additional immune and endocrinological abnormalities evident in the BB rats, the generalizability of these findings to humans is limited.

Human Studies

Research has shown that people who go on to develop type 1 diabetes are more likely to suffer a major family loss or an increase in other stressful life events before diagnosis. Some of these studies have been poorly controlled and were also prone to recall bias, in which the pattern of life events reported may reflect an attempt to find an explanation for diabetes onset rather than a difference in the events actually encountered. However, a more carefully controlled study of life events that avoided problems of recall bias by Robinson and Fuller in 1985 has also shown that people with diabetes had significantly more severe life events within the 3 years before diagnosis than either nondiabetic siblings or matched controls. It is possible that life events experienced over longer time periods may play a role in the etiology of type 1 diabetes. It is clear from prospective studies of islet cell antibodies (ICAs) that many years may elapse between the actions of the possible stress-related causal agents that initiate cell damage and the appearance of symptomatic diabetes.

Clear evidence of the effect of stress on diabetes onset is difficult to establish. Some difficulties include methodological problems and interpretation of the findings that involve expensive, large, prospective studies or a reliance on retrospective methods to identify the relationship between stressful experiences and the onset of the disease. However, even in a seemingly large trial, it can be difficult to delineate the effects of stress if a broad age range of people is recruited into the trial. As discussed by Lloyd et al. in 2005 it is often the case that differences in the type and intensity of life changes are associated with different ages. The relationship between stress and diabetes control is more amenable to study.

Stress and Type 1 Diabetes Control

It is widely recognized by people with diabetes and their clinicians that psychological stress can impair glycogenic control. Theoretically, stress-related hyperglycemia should be greater in type 1 patients (compared to type 2 patients) because type 1 patients have little or no endogenous insulin to offset increased blood glucose levels. Stress may affect diabetes control in at least two ways:

1. A direct psychophysiological effect via sympathetic and pituitary activity resulting in the elevation of catabolic hormone levels and the suppression of anabolic hormones. In people with diabetes, this may result in increased blood glucose levels, although, for a small minority, less readily understood decreases in blood glucose levels result.
2. A behavioral mechanism whereby stress leads to behavioral changes capable of disrupting self-care. For example, the occurrence of unexpected, frustrating events may disrupt the diabetes self-care routines.

Acute Stress and Blood Glucose Control

Pioneering work examining the relationship between stress and diabetes was most often conducted in the laboratory, and the stresses induced were normally acute. In the early 1950s, Hinkle and others induced stress in some of their patients by a psychiatric interview and found changes in the patients' blood ketone levels that remitted when the stress was removed. These researchers carried out a series of studies that showed that individuals without diabetes and individuals with diabetes (both type 1 and type 2 patients were studied) have a metabolic response to psychological stress that included changes in urine glucose, blood glucose, and blood ketones, but the response of those with diabetes was greater. Research in the 1960s included investigations of stress under hypnosis and

examination stress, which resulted in a decrease in blood glucose levels. However, the early studies have been criticized on methodological and conceptual grounds. There was concern that the stressors used were not sufficiently potent or reproducible. Furthermore, the grouping together of heterogeneous patients with type 1 and 2 diabetes and patients with different degrees of blood glucose control in studies of very small groups were also a focus of criticism.

Several seemingly well-controlled acute stress studies conducted in the 1980s reported no significant changes in blood glucose control in response to potential stressors such as mental arithmetic and public speaking. However, in an attempt to meet the criticisms leveled at the earlier studies, these later studies overlooked the possibility that individual differences in response to stress might be real and interesting and not a reflection of methodological inadequacies. More recent studies of experimental stress have examined the physiological mechanisms hypothesized to mediate the relationship between stress and blood glucose control. There is evidence that reduced blood flow to the insulin injection site and insulin resistance over several hours may cause increased blood glucose levels in individuals with type 1 diabetes in response to acute laboratory stressors. There is also evidence that the level of blood glucose rises in some patients and falls in others in response to a laboratory stressor (Stroop test) and that these changes can be largely explicable in terms of changes in injection-site blood flow. Vasodilation at the subcutaneous insulin injection site may in some cases lead to a paradoxical hypoglycemic effect during acute stress via an increased rate of absorption of insulin, an effect that is then counterbalanced to a greater or lesser degree by increases in counterregulatory hormones. More commonly, the absorption of insulin may fall during stress as a result of vasoconstriction and reduced skin blood flow and contribute to hyperglycemia.

Idiosyncratic blood glucose responses that were reliable across a 12-week period in individuals with type 1 diabetes have been reported in response to caffeine and to the competitive playing of a video game. Researchers have therefore begun to consider individual differences in response to stress to be real and interesting and not a reflection of methodological inadequacies. The inconsistent findings of previous research may have arisen at least in part because of differences in the stress responsiveness of the individual patients recruited.

Life Stress and Diabetes Control

Major life events Studies of major life events and diabetes control have produced fairly consistent results

that have suggested that increased life events (over past several months to a year) are associated with raised blood glucose levels, usually measured by glycosylated hemoglobin (GHb) or the related measures of hemoglobin A1 (HbA1) and hemoglobin A1c (HbA1c). These measures reflect average blood glucose levels over the previous 6–8 weeks. In some studies, more life events were reported by groups showing a stronger association between life events and HbA1c levels. This could be due to a perceptual bias that may have led people who experienced a greater disturbance in association with life events to be more likely to recall the life events. It could be that the subgroups did not actually differ in the number of life events reported, but only in their recollection of the events. However, a two-way causal link in which life events cause disruptions in diabetes control, which in turn cause increased life events has been suggested (see [Figure 1](#)). There is evidence that glycemic fluctuations themselves can contribute to behavioral changes. It is now well-established that both hypo- and hyperglycemia can impair cognitive functioning. Cognitive impairment may in turn cause inadvertent behavioral changes (e.g., in poor self-care responses to feedback from blood glucose monitoring), which can affect blood glucose control. Poorly controlled diabetes may also result in mood changes, causing interpersonal conflict and thereby increasing stress levels and associated physiological reactivity. Physical symptoms are also caused by extreme blood glucose levels (e.g., fatigue is often associated with high blood glucose levels).

Figure 1 An elaborated two-way causal model of relationships between life stress and diabetes control. From Bradley, C. (1988). Stress and diabetes. In: Fisher, S. & Reason, J. (eds.) *Handbook of life stress, cognition and health*, pp. 383–431. Chichester, UK: John Wiley.

Hypoglycemic comas may have many consequences, including accidents, job loss, and relationship problems. Such associations are described in the stress–blood glucose model shown in [Figure 1](#).

The practice of aggregating life stresses and blood glucose levels across time, incorporated by the majority of the life event studies, assumes minimal within-individual variation in stress and in blood glucose response. Such assumptions are not supported by common experience or by the literature, which suggests that the stress experienced varies in individuals from day to day. Information about the variability of blood glucose levels is lost when measures of GHb are used that give only an average of blood glucose control. Hypoglycemia is not reflected in GHb measures because of its transient nature. Multiple observations of stress are required, together with serial blood glucose measurement. Recent research has focused on the relationship between minor daily events and diabetes control (using serial blood glucose measurements) in order to overcome these methodological limitations.

Minor daily events Investigations of minor events have provided more interpretable results with studies reflecting individual differences in response to stress that were also seen in some of the laboratory-based acute stress studies. Although the overall picture suggests that increased daily stress correlates with increased blood glucose levels in people with type 1 diabetes, an examination of individuals' blood glucose responses to stress indicates that some people display blood glucose reactivity to stress and some people do not. In a 1990 study by Halford et al., approximately one-half of the 15 participants with type 1 diabetes had significant associations between stress and blood glucose levels independent of the effects of diet and exercise self-management. In a small 2000 study by Kramer et al., two of the nine participants had significant correlations between stress and HbA1c, whereas six participants exhibited significant associations between stress and daily level or variability of glucose readings. In a larger 2004 study by Riaz et al. with 54 participants, in approximately one-third of the sample stress was significantly associated with either same- or next-day blood glucose levels. In those people who display stress reactivity, most show an increase in blood glucose but there is also evidence to suggest that a smaller proportion of people show a decrease in blood glucose. Therefore, in order for people with type 1 diabetes to take appropriate action to prevent or correct stress-related disruptions in diabetes control, they need to discover empirically how their own blood glucose levels respond to different kinds of stress.

Investigation of Correlates of Stress Reactivity

There is some evidence to suggest that people with poor control of their diabetes may be more stress reactive (stress being either laboratory-induced or in the form of life events). This supports the model in [Figure 1](#). There is also evidence from Stabler et al. in 1986 that children with type 1 diabetes who are classified as having type A personality characteristics show elevated blood glucose levels after playing a stressful video game, whereas type B children with type 1 diabetes showed a decrease in blood glucose levels. However, there is also evidence that internality and self-esteem did not relate to stress reactivity in the group of women with type 1 diabetes studied by Aikens and colleagues in 1994. It is likely that individual differences in stress response are mediated by both physiological and psychological processes. For example, Riaz et al. in 2004 found that stress-reactive individuals, compared to non-stress-reactive individuals, had both high HbA1c values and significant relationships between emotion-focused coping and blood glucose levels. However, further research is necessary to clarify the associations between these variables and stress reactivity.

Stress Management Training and Type 1 Diabetes Control

The overly simple model of life stress causing raised blood glucose levels has inspired the use of stress management training as an aid to diabetes control. There is now self-help guidance available in a book by Surwit and Bauman published in 1994 for people with diabetes who are interested in achieving better diabetes control through stress management training, in particular, relaxation training. Relaxation is thought to decrease the levels of both cortisol and catecholamines and, hence, is expected to prevent stress-induced increases in blood glucose levels.

The research to date supports the view that stress management techniques may be valuable for aiding diabetes management in some people but not in others. It has been suggested that relaxation techniques are unlikely to do harm except when blood glucose is already tightly controlled and the insulin dosage is not appropriately reduced to balance the effects of relaxation on insulin requirements (which may well be reduced) and/or when used at a time when blood glucose is already low ($<4 \text{ mmol l}^{-1}$) and there is a risk of hypoglycemia. It is important to take the precaution of measuring blood glucose immediately before all relaxation training or practice sessions. Twenty minutes of relaxation can lead to a drop in blood glucose by as much as 3 mmol l^{-1} .

Such a substantial fall is likely only if blood glucose is well above the normal range of 4–6 mmol l⁻¹ to start with and probably results from a suppression of catecholamine secretion. It is recommended that relaxation training should not be conducted at blood glucose levels below 4 mmol l⁻¹ because of the risk of hypoglycemia. Relaxation training might be continued if the anticipated reduction in blood glucose were counteracted with the pretraining intake of slow-release carbohydrate (e.g., an apple). The further precaution of measuring the blood glucose after a relaxation session, before leaving the therapist's office, is also recommended to avoid the risk of hypoglycemia while traveling home.

Several studies have reported some success with improvements in diabetes control following relaxation training (sometimes involving electromyograph, EMG, biofeedback) in people with type 1 diabetes. There is evidence to suggest that relaxation training is least useful for those people whose glycogenic control is good to start with and is most useful when used by people who not only have poor control of their diabetes but who feel that stress disrupts their diabetes control and who are currently experiencing stressful events. Although some studies have found no significant differences between relaxation and control groups in HbA1c levels or insulin requirements after relaxation training, information about the variability of the individual patients was rarely reported. In addition, the lack of selection of patients likely to benefit from relaxation training may be responsible for the nonsignificant findings of some studies.

What is emerging from the studies of relaxation training in people with type 1 diabetes is that it is most demonstrably useful for those who are showing stress-related disturbance of blood glucose control at the time. An assessment of patients' stress reactivity before embarking on relaxation training in future studies will help in the identification of patients most likely to show benefit from relaxation training. To date, most studies have incorporated biofeedback in the relaxation training. Relaxation instructions alone would be more practical and less costly. The evaluation of low-technology forms of relaxation training in patients shown to be stress reactive would be a useful contribution to the state of present research. Such an evaluation needs to take account of the fact that the benefits of relaxation training for blood glucose control will only be apparent during periods of stress when stress-reactive relaxation-trained individuals are expected to have more stable blood glucose control than stress-reactive individuals who have not been trained. Improvements in blood glucose control will be more apparent if recruitment

to such a study is restricted to individuals who show increased blood glucose under stress.

Introduction

Animal Research into Stress and Eating Behavior

Human Research into Stress and Food Intake

Mechanisms Relating Stress to Eating

Summary

Glossary

<i>Dieting</i>	Deliberate modification of food intake in order to lose weight.
<i>Disinhibition</i>	Acute loss of cognitive control over food intake.
<i>Emotional eating</i>	Eating in response to emotional cues.
<i>Hyperphagia</i>	Eating more than usual.
<i>Hypophagia</i>	Eating less than usual.
<i>Restrained eating</i>	The chronic tendency to try to exert control over food intake. It was first measured with the Restraint Scale, which in addition to items reflecting attempts to diet, included loss of control over eating and weight fluctuation. More recent measures of restraint have placed greater emphasis on the dieting component, conceptualizing the episodes of loss of control as forms of disinhibition of restraint, rather than part of the core concept.

Introduction

There is a widespread belief that stress influences eating behavior, but considerable uncertainty about the direction of the effect, i.e., whether stress increases or decreases food intake. An analysis of the physiology of stress would lead us to expect decreased eating, because stress slows gastric emptying and increases energy substrate levels, which should reduce appetite. Stress also promotes behaviors designed to cope with or escape from the source of stress, and under these circumstances, eating might be accorded a lower priority. In contrast, the literature on human reactions to stress suggests that it can be associated with increased food intake or a shift toward a higher fat diet.

Our knowledge of stress and eating comes from diverse areas of research, including clinical studies on the etiology of obesity and eating disorders, laboratory studies on dieting and the regulation of food intake, surveys of stress and health-related behaviors, and animal work on stress responses. The diversity of this literature means that there is great variation in the sources and intensity of the stressors that have been examined, the circumstances in which food is consumed, the quality of dietary information that can be gathered, and the populations that have been studied. On this basis, it may not be surprising to find that the links between stress and eating appear to be complex.

Animal Research into Stress and Eating Behavior

Animal research appears to offer the ideal opportunity to examine the general, physiologically mediated effect of stress on food intake. Animals can be exposed to stress or a control condition; stressors can vary in quality, intensity, or duration; the animal's deprivation state can be manipulated; and the type of food supplied can be varied. However, to date, this research has produced an extraordinarily inconsistent set of results. Much of the early work used rats as the experimental subjects and tail pinch as the stressor and typically found that food intake was increased by this procedure. However, tail pinch is now thought to represent an atypical stressor, if it is even stressful at all, and increased eating may be part of a general increase in oral behaviors, rather than a specific behavioral response. Other stressors have included electric shock, noise, immobilization, isolation, housing changes, cold water swims, and defeat in fights, with varied effects on food intake from study to study, ranging from substantial increases in food intake in some studies to substantial decreases in other studies. Attempts to relate the direction of the effect on eating to the characteristics of the stressor have so far been unsuccessful, partly because many of the stressors have been used in only a handful of studies, whereas electric shock, which has been used often, shows inexplicable variation. To date, the only possible consistencies are that chronic stressors appear to be more likely to have a hyperphagic effect and social stressors may be more hyperphagic than physical stressors.

Recent animal research has provided some more fruitful results by considering individual differences in susceptibility to stress. For example, rats that are resistant to dietary-induced obesity seem to be

hyperresponsive to stress, at both the neurohormonal and behavioral level, compared to those rats that become obese when allowed to overeat. Intriguingly, it has recently been shown that it is the ability to choose from separate sources of energy-dense palatable foods that confers stress resilience, rather than an increase in energy-dense food intake per se.

Human Research into Stress and Food Intake

Human research on stress and food intake has come from several research traditions. Naturalistic studies usually investigate community samples and attempt to gather information on food intake at high- and low-stress periods of life. The focus in these studies, as in most of the animal research, has been on the general effect of stress on eating over the short or medium term. Laboratory studies usually administer a stressful procedure in parallel with an eating task, then covertly assess food intake. The emphasis therefore is on the acute effects of stress. Most of the laboratory studies have taken an individual differences perspective, examining stress-related eating in relation either to weight or dietary restraint.

Naturalistic Studies

There is a variety of naturally occurring, but predictable, stressful circumstances that can provide an experimental context in which to study stress-related variations in diet. School or university examinations have been used as the stressor in several studies, and periods of high work stress in others. Food intake is recorded either in a diary record kept by the study participants or with a 24-h recall procedure. The food records are then analyzed to obtain estimates of intake of energy and nutrients. Biological measures such as weight or blood lipids have been included in some studies to provide another indicator of dietary change.

Among the published studies there is one element of consistency, namely, none of them has found lower food intake, on average, during the higher stress time. Likewise, there is little evidence for lower weight or lower serum cholesterol under stress. Otherwise, the results have been divided. In some of the studies, both overall energy intake and intake of fat are higher at the high-stress time. In other studies, there is enormous individual variability, but no average difference in energy intake between low- and high-stress periods. In a recent study, mood and eating were sampled at random intervals in students awaiting an exam in a few days. They reported more negative moods, together with an increase in reported eating for

distraction, relative to an exam-free control group. However, no differences were found for food intake or choice. In another study, which unlike many naturalistic studies was not confounded by the passage of time, high workload in department store workers was associated with higher fat, sugar, and total energy intake, but only in people who habitually restrained their food intake.

In a recent survey of a large number of U.S. teenagers, depressive symptoms were associated with perceived barriers to healthy eating, meal skipping, and more disordered eating, although the only significant change in diet appeared to be increased consumption of soft drinks in more depressed school children. In a Finnish population-based study of adults, stress-driven eaters ate more energy-dense high-fat foods and had higher body mass indices. Other studies have suggested a link between stressful life events and higher body weight. However, this does not necessarily imply increased eating, since reduced physical activity may also be an important contributor. For example, parents of a child recently diagnosed with cancer gained more weight over 3 months compared to parents with a healthy child. However, since they also reported both less physical activity and lower energy intake, it is likely that most of the weight gain was attributable to a stress-induced reduction in activity.

The balance of evidence so far has to be that stress in everyday life rarely appears to have a hypophagic effect, and it may, in some people and some circumstances, have a hyperphagic effect.

One explanation for the variability in results is the poor validity and reliability of measures of food intake. Keeping a food diary is an onerous task, so compliance is poor, and even among those who return a diary there are likely to be errors: people forget foods, are not able to assess quantities accurately, and often complete the diary well after the eating event. Diary keeping is also reactive, i.e., it is likely to influence the behavior being monitored, because of either the increased attention or the wish to present a good record to the experimenter. Unscheduled 24-h recalls avoid the problem of reactivity, but are still susceptible to forgetting and misreporting, as well as providing a much more restricted snapshot of food intake. Methodological problems also arise from translating typical information on food intake (e.g., "I had a medium-sized cheese sandwich, but I am not sure if the bread was spread with butter or margarine, or what type of cheese it was") into any meaningful value for energy and nutrient intake. Even expert dietitians are reduced to estimating and guessing a good deal of the time. The poor data quality means that any results must be evaluated cautiously, and

results from small samples could easily give a misleading impression.

A second explanation for variability in the results is the different kinds of stressor. The animal literature suggests that physical stressors might be more likely to elicit hypophagia, and social stressors, hyperphagia. In human experiences, the stress of surgery for a hernia, which was used in one study, is qualitatively and quantitatively different from the stress of an examination or a period of long working hours used in others, and this difference could well have an effect on food intake. Some stressors could occur together with changes in circumstances that enforce a change in eating behavior even if there is no direct effect of the stress on appetite. However, at present there are too few human studies to make any systematic analyses of the differential effects of different types of stressor.

The third explanation is that individuals might vary in their response to stress, and the admixture of response types could differ from study to study. Few naturalistic studies have taken an individual difference perspective, but those that do indicate that there are important individual differences that need to be considered in examining the effects of stress. In one study, middle-aged men and women kept daily stress diaries over several weeks and at the same time recorded whether, on that day, they had eaten more, the same, or less than usual. The pattern of results showed that most individuals were consistent in their reactions to stress, with some consistently eating more on higher stress days, and others consistently eating less. Over the sample as a whole, the hypophagic response predominated. Similarly, in surveys that ask respondents about how stress affects their eating, the majority report some effect of stress, with approximately equal proportions saying that they eat more and eat less while under stress.

Laboratory Studies

Most laboratory studies have been based on the idea that the biologically natural response to stress is hypophagia, but that individuals who are either overweight or highly restrained eaters are unresponsive to their internal signals. Participants are therefore characterized according to these features and hypothesized to respond differently to stress.

Laboratory studies have used a range of stressors, including unpleasant films, false heart rate feedback, and threat of public speaking. In the typical design, participants are exposed either to the stressor or to a control procedure, and food intake is assessed covertly, often disguised as a taste test in which participants are asked to taste and rate some flavors of a palatable

food such as ice cream. The amount that is eaten is recorded accurately by preweighing then reweighing the food containers.

Obesity and stress-induced eating The clinical interest in stress-related eating stemmed from the psychosomatic theory of obesity, which suggested that for the obese, eating met emotional rather than nutritional needs, and that the tendency toward emotional eating explained why they had become obese in the first place. Eating was hypothesized to provide reassurance, and hence stress was predicted to trigger higher-than-usual food intake, so-called emotional eating. There is no doubt that many obese people report that they eat more under stress, but these clinical reports need to be examined in controlled studies, both to establish their validity and to see whether stress-related eating is specific to obesity.

In practice, laboratory studies on stress-related eating in the obese have produced mixed results, with some finding higher intake under stress in the obese and others not. There has also been variability in naturalistic studies, but on balance, there is probably enough evidence to conclude that obesity is an indicator of a higher risk of stress-induced hyperphagia, or at least a lower likelihood of stress hypophagia.

The other side of the psychosomatic theory was that eating would have an anxiolytic effect, and this has received less support. Clinically, many obese people admit that any solace they derive from eating is transient and rapidly followed by shame and regret at not having showed more self-control. In laboratory studies there has been no evidence that eating successfully reduces emotional arousal. These observations have largely discredited the basic idea of the psychosomatic theory, the idea that obesity represents a disorder of emotional reactions. However, there is still interest in the idea that the obese have a reduced sensitivity to internal satiety cues, and the fact that they do not show stress hypophagia may be a consequence of this lack of internal responsiveness.

Stress, restraint, and emotional eating In 1972, a radical alternative to the psychosomatic theory of obesity was proposed, namely, that any abnormalities of eating observed in the obese were not pre-existing tendencies, but a consequence of the steps that they were taking to reduce their weight. At first the emphasis was on the effects of maintaining a body size below the hypothesized set-point. This was superseded by Restraint Theory, which proposed that one of the important determinants of food intake regulation was the tendency toward restrained eating – the combination of concern about eating and weight fluctuation. Most obese people and a significant proportion of normal-weight adults, particularly women,

are constantly trying to restrict their food intake in order to reduce their weight. The habit of trying to restrict food intake could have the effect of changing people's relationship with food, such that the usual cues to hunger and fullness become less effective in regulating their eating behavior. Restrained eaters were found to limit their food intake at times when external or emotional pressures were low, but at other times, they would abandon restraint and eat to capacity, so-called disinhibition.

One of the early observations on restrained eating was that, among individuals who experienced anxiety in response to a stressor, food intake was increased among the restrained eaters and decreased among unrestrained eaters. This general pattern, involving an interaction between stress and restraint in predicting food intake, has proved extremely robust. Across many different studies, with a wide range of stressors, restrained eaters almost always eat more in the stressed than in the unstressed condition. In contrast, unrestrained eaters show more variation, sometimes eating the same amount and sometimes eating less while under stress. The results of these laboratory studies have been strikingly consistent in an area in which most of the work is notable for its inconsistency.

There is now a growing interest in examining the role of restraint in predicting individual differences in responses to stress in real-life studies, and so far the results are consistent with the laboratory studies in showing that restrained eaters are more likely to report stress-induced hyperphagia, whereas unrestrained eaters are more likely to report hypophagia. These findings are supported by results from quantitative studies using psychometric measures of restraint and emotional eating, which found that higher restraint was associated with higher levels of emotional eating.

Recently there has been a resurgence of interest in the role of negative affect and emotional eating as predictors of problematic eating and poor control of weight. One reason for this has been the realization that earlier psychometric measures to some extent conflated restrained and emotional eating. Dietary restraint was measured in most studies by the Restraint Scale, which includes the tendency for eating to be disinhibited by emotional states. In one laboratory study, when separate scales were used to measure restraint and emotional eating (Dutch Eating Behaviour Questionnaire), the latter was the better predictor of stress-induced eating. That study tested the effects of public-speaking stress on intake of a variety of foods from sweet, salty, and bland taste categories, and in addition, high- and low-fat examples within those sensory groups. Analyzing effects by taste category may be important because stress and mood have been shown to affect taste perception. The food was

presented as a buffet-style meal during preparation of the speech task. Stress did not alter overall intake; however, stressed emotional eaters ate more sweet, high-fat foods (chocolate and cake), and a more energy-dense meal, than either unstressed emotional eaters or nonemotional eaters in either condition. This supports the survey findings that sweet, fatty foods such as chocolate may be preferentially sought during stress or negative affect, at least in a subgroup of susceptible individuals (see next section).

Emotional eating may underlie previous reports that dietary restraint or female gender predicts stress-induced eating. Moreover, emotional eaters may be more susceptible to effects of stress: women who ate more from a selection of snack foods after a stressful task also showed the greatest release of the stress-sensitive hormone, cortisol, and more stress-induced negative affect. These high reactors also showed a preference for sweet foods. So it seems that emotional eaters may be more likely to experience mood disturbance when challenged.

Emotional and disinhibited eating and dietary restraint could interact: the latter seems to contribute to stress-induced eating of sweet, fatty foods by women classified as disinhibited eaters. Recently, it was shown that highly restrained/low emotional eaters ate more chocolate after both ego-threatening and cognitively demanding tasks, whereas low restraint/high emotional eaters ate more chocolate only after the ego threat.

Emotional responses to food may also be sensitive to expectations. In a laboratory study, women were asked to rate various emotions immediately after eating small amounts (5 g) of nine different foods, three being low in energy, three medium, and three high in energy (in counterbalanced order). Intensity of negative moods (sad, ashamed, anxious, sleepy) increased with increasing energy density of the foods, and more so for overweight than for normal-weight women. Moreover, medium- and high-energy foods were rated less healthy and more dangerous than low-energy foods. These effects were independent of rated pleasantness of the foods. It is probable that these effects were psychological rather than physiological in nature, given the small amounts of food eaten and the immediacy of the ratings. The negative effects of the high-energy foods presumably reflect concerns about their impact on health and weight gain. Interestingly, though, stronger increases in negative mood were seen for women reporting greater tendencies to eat in response to emotional state.

These results are similar to the finding that self-identified chocolate addicts felt guiltier after eating chocolate than a control group. The chocolate addicts

also reported worse mood before eating the chocolate. By contrast, in another study in healthy men, experimental induction of sadness decreased appetite, whereas when the men were cheerful, the chocolate tasted more pleasant and stimulating and more of it was eaten. This gender difference is likely to be confounded by dispositional and attitudinal differences.

Stress and Food Choice

Human studies on stress and meal patterns/food choice Studies of stress and eating usually focus on the amount of food consumed, but stress might also affect food choices or meal patterns. In the naturalistic studies that showed increased energy intake, there was also an increase in the proportion of energy from fat. This could reflect an increased preference for fatty foods, or alternatively a different meal pattern. In most Western countries the proportion of fat in meal-type foods tends to be lower than in snack-type foods. If stress induced a shift from meals to snacks, this would be reflected in a higher fat intake and might also increase the total energy intake, since higher fat foods have a higher energy density.

In most naturalistic studies, it is not possible to distinguish meal pattern changes from food choice changes, because the data are presented in terms of daily intake of nutrients, without any information either on foods eaten or timing of consumption. Most laboratory studies have also failed to address the food choice issue, because they present only a single type of food. However, there is some evidence that sweet, high-fat foods are the ones most likely to show an increase (see previous section), whereas fruit and vegetables appear to be avoided during stress. In a study of health behaviors in 11- to 13-year-old schoolchildren in London, greater perceived stress was associated with more fatty food intake, less fruit and vegetable intake, more snacking, and a reduced likelihood of daily breakfast consumption.

A survey of possible changes in food choice during stress among 212 students revealed an interesting pattern of effects of stress, which was partly independent of whether participants were grouped as reporting eating more, the same, or less overall when stressed. That is, sweets and chocolate were reported to be eaten more under stress by all groups, even those eating less overall; conversely, intakes of fruit and vegetables, and meat and fish, were reported as less or unchanged under stress in all groups. The changes for the staple food, bread, matched the overall group self-perceptions of changes in eating due to stress. These data imply that mechanisms governing effects of stress on food choice may be somewhat separate from those influencing overall appetite under stress

and that foods such as sweets and chocolate may be particularly selected in stressful circumstances.

Chocolate: A unique mood-enhancing food? Chocolate does seem to have a special place in the relationship between food choice and mood: it is a widely liked food, and people often report choosing to eat chocolate during stress. Indeed, experimenters frequently choose chocolate or chocolate-containing foods as the test foods in studies looking at stress-induced eating, reflecting a cultural awareness of its value as a mood enhancer. There are popular notions, perpetuated both in the lay and scientific media, that chocolate contains psychoactive chemicals, such as phenylethylamine and cannabinoids, that are responsible for its effect on mood. However, for reasons of quantity and availability to the brain, these compounds are not likely to alter mood when obtained from chocolate. Nevertheless, it has recently been shown that the methylxanthines in chocolate, caffeine, and theobromine can indeed improve mood (hedonic and energetic dimensions) as well as mental function. Perhaps the effects of these compounds underlie a curious recent report showing that mothers who said they ate chocolate every day during pregnancy subsequently rated their babies' temperaments more positively when aged 4–9 months. These mothers did not appear to have distinctive personality traits that might otherwise explain the rating difference.

Chocolate has other characteristics that could be mood enhancing. It is high in fat and sugar and so would be likely to activate opioidergic hedonic and dopaminergic reward pathways (see next section). It is also low in protein (3–6% of energy), so if eaten in sufficient amounts on an empty stomach might conceivably enhance mood via increased synthesis of the brain neurotransmitter serotonin, as outlined in a later section. Finally, chocolate could also acquire secondary reinforcing or mood-enhancing properties by association with its use as a treat or gift and convivial social interaction. However, it should be remembered that in those who may consider chocolate to be a dangerous temptation that threatens their weight control, eating it can have negative consequences for mood.

Mechanisms Relating Stress to Eating

Neurohormonal Pathways

Eating food activates brain pathways involved in reward, and so might be expected to have a positive effect on mood. Furthermore, some of the ingested nutrients could alter the function of neurohormonal systems involved in coping with stress. We now

consider the main pathways that appear to underlie such effects (see **Food Intake and Stress, Human; Neuroendocrine Systems**).

Opioids Endogenous opioid neuropeptides are released during stress and are known to be important for adaptive effects such as tolerance of pain. They are also involved in motivational and reward processes in eating behavior, such as stimulation of appetite by palatable foods. This would tend to suggest that there would be a link between opioid action, stress, and food choice. Perhaps the best evidence for opioid involvement in an interaction between stress and eating is the finding that, in animals and human infants, ingestion of sweet and fatty foods, including milk and even a nonnutritive sweetener, alleviates crying and other behavioral signs of distress. This stress-reducing effect of sweet taste has been shown to depend on opioid transmitter systems.

In human neonates, sucking on a pacifier (dummy) or brief exposure to breast milk is also very effective in reducing signs of pain or spontaneous crying. Interestingly, as babies grow older, sweet taste becomes less effective at calming than pacifier sucking, which might reflect a maturational separation of taste and emotion or a difference in opportunities to learn the instrumental emotional value of the two experiences.

The extent to which adults (whether rat or human) retain an analgesic effect of sweet taste remains controversial. Using the cold pressor test (holding the hand in very cold water), pain threshold latency was extended by concurrent sweet taste in 8- to 11-year-old children. In adults, pain tolerance, but not threshold, was increased by prior tasting of a sucrose solution. However, perceived palatability (liking) may be important, since in one study it was found that only highly liked foods (chocolate chip cookies), and not bland or disliked foods, were able to increase pain tolerance in female students when eaten beforehand. It is tempting but speculative to conclude that adults may select sweet, fatty, palatable foods for opioid-mediated relief of stress.

Dopamine The neurotransmitter dopamine is thought to be the major chemical messenger for reward in the brain. The availability of dopamine receptors (D_2) in part of the brain reward pathway, the striatum, has been shown to be inversely correlated to body mass index. This finding has led to the suggestion of a neurochemical trait that elicits overeating of palatable foods so as to enhance dopamine release – a neural predisposition for comfort eating. In support of this, energy-dense snack foods appear to reinforce greater effort to obtain them in obese than in non-obese women. Young children of obese parents

also show greater enjoyment of food as well as higher preference for high-fat energy-dense foods than offspring of non-obese parents. It may also be relevant that binge eating and other eating disorders are associated with greater risk of substance abuse, as well as susceptibility to negative affect, possibly linked by the fact that dopamine also mediates stress sensitivity, depression, and reinforcement of drug-taking habits.

Serotonin The neurotransmitter serotonin has been implicated in mood disorders, anxiety, and stress coping, as well as in eating behavior. Synthesis of serotonin (or 5-hydroxytryptamine [5-HT]) depends on dietary availability of the precursor essential amino acid, tryptophan (TRP), due to a lack of saturation of the rate-limiting enzyme, tryptophan hydroxylase, which converts TRP to the intermediate compound 5-hydroxytryptophan.

An important complication is that TRP competes with several other amino acids, the large, neutral, primarily branched chain amino acids (LNAA), for the same transport system from blood to brain. If the protein content of a meal is sufficiently low, such as 5% or less total energy as protein, then relatively few amino acids will be absorbed from the food in the gut. At the same time, insulin will stimulate tissue uptake of competing amino acids from the circulation, and the plasma ratio of TRP to those amino acids (TRP/LNAA) will rise, favoring more TRP entry to the brain. Conversely, a high-protein meal, which would be less insulinogenic, results in absorption of large amounts of competing amino acids into the blood, especially the branched-chain amino acids, leucine, isoleucine, and valine. On the other hand, TRP is scarce in most protein sources and is readily metabolized on passage through the liver; thus, the plasma ratio of TRP to competing amino acids falls after a protein-rich meal.

The possibility that a carbohydrate-rich, low-protein meal could raise 5-HT function gave rise to the proposal that some depressed people may self-medicate by eating high proportions of carbohydrate. It was suggested that this would lead to increased 5-HT release in a manner reminiscent of antidepressant drugs, which enhance aspects of 5-HT function by inhibiting removal of 5-HT from the synaptic cleft between nerve cells. For the most part, early behavioral and pharmacological evidence for such a phenomenon was not very convincing.

Nevertheless, recent research provides some further support for beneficial effects of carbohydrate-rich, protein-poor meals on mood and emotion in some people. When participants were divided into high or low stress-prone groups, as defined by a questionnaire measure of neuroticism, carbohydrate-rich,

protein-poor meals (which raised plasma TRP/LNAA ratios) prior to a stressful task were found to block task-induced depressive feelings and release of the glucocorticoid stress hormone cortisol, but only in the high stress-prone group. This finding was replicated using high- vs. low-TRP-containing proteins (α -lactalbumin and casein, respectively). It was argued that because stress increases 5-HT activity, the poor stress coping of this sensitive group might indicate a deficit in 5-HT synthesis that is improved by this dietary intervention.

Neuroendocrine systems A critical neurohormonal system mediating the effects of stress on energy flux and appetite is the hypothalamic-pituitary-adrenocortical (HPA) axis. Neural stimulation of selected nuclei in the hypothalamus of the brain leads to corticotropin-releasing hormone (CRH) acting on the pituitary gland to release adrenocorticotrophic hormone (ACTH), which in turn stimulates release of the steroid glucocorticoid hormone cortisol from the adrenal glands. In animals, CRH is known to mediate the suppression of food intake by severe stressors. On the other hand, exogenous glucocorticoids stimulate appetite by acting on the hypothalamus to inhibit CRH release.

The involvement of the HPA axis in the influence of stress on eating behavior seems likely for several reasons, including (1) glucocorticoid hormones substantially affect energy substrate mobilization and metabolism, increasing lipolysis, proteolysis, and gluconeogenesis while protecting hepatic glycogen stores; (2) the circadian rhythm of HPA axis responsiveness is dependent on patterns of food ingestion; (3) normal meals containing at least 10% protein as energy activate the HPA axis and release cortisol in humans; and (4) acute food deprivation suppresses the HPA axis response to stress.

Furthermore, most animal models of obesity, genetic or otherwise, depend on an intact HPA axis, and disruption of its function may underlie at least some human obesity, in particular increased visceral adiposity, especially among obese patients suffering from anxiety and depression. The eating disorders bulimia and anorexia nervosa are also associated with hypercortisolemia and disrupted HPA axis activity even in the absence of undernutrition. An inability to cope with stress, coupled with chronic activation of appetite-suppressing CRH, is one psychobiological model proposed for anorexia nervosa.

Another hormone that may be involved in integrating HPA axis activity and food intake is the adipocyte hormone leptin. Leptin is synthesized in adipose tissue, and plasma levels correlate strongly with fat mass in humans, with consistently higher levels in

women than in men independent of body composition. In genetic rodent models, obesity has been shown to be associated with the absence of either leptin (ob/ob mice) or its receptor (db/db mice; fa/fa rats). Glucocorticoids administered to humans cause gradual and sustained increases in plasma leptin, and leptin in turn seems to inhibit the activity of the HPA axis. Indeed, normal release of leptin and activity of the HPA axis are inversely related. Leptin may contribute to the regulation of energy balance in part by inhibiting activity of neuropeptide Y, which is known to stimulate feeding via an action in the hypothalamus. However, acute physiological changes in neither glucocorticoids nor short-term food intake seem directly to alter circulating leptin levels. Instead, leptin may be important for longer term regulation of food intake. Moreover, chronic stress may disrupt the balance between leptin and the HPA axis, leading to abnormal eating. The precise nature of the change in eating under chronic stress – under- or overeating – may depend on individual predispositions (see next section).

In stressed people, raised levels of cortisol contribute to abdominal obesity, which in turn promotes insulin resistance. However, insulin resistance may increase the likelihood that high-carbohydrate, low-protein foods would raise brain TRP and 5-HT levels because of increased levels of plasma free fatty acids, which, by competing for binding to albumin, could result in more unbound TRP in plasma. This might underlie recent findings that insulin-resistant people are less prone to suicide and depression, both of which are believed to be increased by low 5-HT function. However, animal studies suggest that this could also depend on normalization of HPA axis function and release of cortisol by feedback from increased abdominal adiposity and intake of high-carbohydrate, energy-dense foods, with a possible resultant improvement in mood. Similarly, in humans, patients with seasonal affective disorder (a form of depression) show increased insulin resistance in the winter, together with a greater predilection for sugar-rich foods, both of which might help alleviate their mood symptoms. Unfortunately, despite this possible protective effect, insulin resistance is a substantial risk to health by promotion of cardiovascular disease.

Biobehavioral Pathways

Theoretical considerations and empirical results indicate that the mechanisms linking stress to changes in food intake are far from straightforward. **Figure 1** illustrates the three principal pathways that have been implicated in the work in this area. In the center is the simple biological pathway whereby

Figure 1 Biobehavioral pathways linking stress and diet.

the physiological effects of stress inhibit the physiological features of hunger (or perhaps mimic the effects of satiety) and hence modify appetite and food intake. Animal research has generally been used to test this pathway since it is assumed that animals' food intake is more directly controlled by the basic drives of hunger and satiety. From present evidence it would seem that some stressors probably induce hypophagia and others hyperphagia, implicating a more complex pathway from stress to food intake even in animals. Humans have the advantage as research subjects that they can tell us about their subjective experience, yet few studies have incorporated measures of hunger or satiety to address this issue. At present, therefore, there is little direct evidence for the hypothesized physiological depression of hunger. The best evidence available from human studies comes from the studies of food intake among normal-weight, nonrestrained eaters. In the laboratory, unrestrained eaters either are unaffected by stress or eat slightly less, which is somewhat supportive of a reduction in appetite, at least in some situations, and for some foods.

A second pathway (shown at the bottom of [Figure 1](#)) results from consideration of the broader effects that stressors have across a range of aspects of life. In real life, stress motivates people to deploy resources toward dealing with the source of stress (so-called problem-focused coping). This may mean that longer term goals like dieting or healthy eating are temporarily set aside, with consequent effects on food choices. Food intake should increase most in those who were normally restrictive, so women, healthy eaters, and dieters should

show the strongest hyperphagic response to stress. This idea is given some support from the higher food intake in stressed restrained eaters, the higher fat and energy intake under stress among women in some of the naturalistic studies, and the observation that energy intakes increase most among those who normally have a low energy intake.

The third pathway, shown at the top of [Figure 1](#), relates to the fact that stress also comes with an emotional coloring, so coping efforts are deployed to deal not only with the source of stress, but also with the emotional state (emotion-focused coping). For some people, especially those who are usually self-denying with food, food may have a significant reward value and may be used to provide emotional comfort. Women in particular often describe food in terms of treats and rewards, and the potential comfort to be derived from sweet foods is deeply enshrined in contemporary culture. Clearly this idea has echoes of the discredited psychosomatic theory of obesity, but it should be remembered that it was rejected not because of the absence of emotional eating, but because eating did not appear to be a successful anxiolytic. Other emotional coping strategies are equally unsuccessful in the longer term (e.g., alcohol, smoking), but that does not prevent the smokers, drinkers, and stress eaters from feeling that their habits serve a comforting role. In the field of eating disorders, excessive eating has been hypothesized to provide escape from self-awareness, which is especially valued in response to ego-threatening stressors, so the idea that eating has a role, functional or dysfunctional, as an emotional coping strategy may have

been rejected prematurely. If emotional eating is part of a stress-coping repertoire, it should be more common in restrained eaters, for whom food has a higher emotional value, and that of course is observed in all of the laboratory studies.

Figure 1 also depicts a likely final outcome of stress on diet, as discussed in the previous sections. That is, for multiple reasons, including sensory pleasure, modulation of neurotransmitter control of mood, and stress coping, susceptible stressed people may end up choosing energy-dense, sweet, fatty foods that will lead to a less healthy diet and possibly weight gain.

Finally, in real life, stresses are not usually single, transient, and novel, as they are in the laboratory. They are prolonged or repeated, they wax and wane, and they can become a familiar part of the landscape. This means that stress reactions are likely to be modified over time. Adaptational processes should be triggered to protect body fat stores; if stress induces hypophagia in the short term, then in the longer term, the loss of body fat should upregulate appetite and restore food intake to normal levels. Few human studies have looked at the effect of repeated stress exposures on eating, but animal studies show that stress-induced hypophagia diminishes with repeated stress exposures. The inclusion of this dynamic perspective adds yet another dimension to an already complex process.

Summary

In summary, the relationship between stress and eating is a complex one, moderated in humans not only by the type of person, the type of stress, and the types of foods that are available, but also by the dynamic relationship between the internal milieu and behavior over time. There is increasing evidence to support the view that some people are particularly susceptible to eating more sweet, fatty, energy-dense foods during stress. Possible explanations can be found at both the psychological and physiological level, but in either case it is probable that such a change in eating behavior helps the individual to cope with stress. Unfortunately, this change in diet may

also result in weight gain, particularly abdominal obesity, and increased risk of cardiovascular disease.

This fascinating area is likely to challenge clinicians and researchers for some time to come, but it also provides one of the richest areas for demonstrating the importance of integrating biology and psychology to understand human behavior.

Introduction

Biological Basis of Stress Eating

Practical Treatment of Stress Eating

Conclusion

Glossary

<i>Behavioral modification</i>	A specific set of counseling techniques using specific tools to change an individual's behavior by altering habitual thoughts and activities in specific situations.
<i>Body mass index (BMI)</i>	The formula of weight (in kilograms)/height (in meters) squared that is used to quantitate medical overweight and obesity. Healthy BMI = 18.5–24.9; Overweight = 25–29.9; Class I Obesity = 30–34.9; Class II Obesity = 35–39.9; Class III Obesity = 40 and above.
<i>Central adiposity</i>	Body fat concentrated in the abdomen; even in the absence of overweight or obesity, this may alone increase cardiovascular risk.
<i>Lifestyle changes</i>	The stepwise substitutions of unhealthy behaviors with more healthful ones, with the goal of improving health, including weight management.
<i>Readiness</i>	An index of individual willingness and motivation to make lifestyle changes leading to better health.
<i>Stress</i>	A biological condition altering brain and metabolic functions as the body responds to a noxious or life-threatening stimulus.
<i>Stress eating</i>	Overeating with a perceived lack of control in response to behavioral stressors; also called emotional eating.

Introduction

Over the past 3 decades, the surging numbers of overweight and obese individuals worldwide have prompted the use of the term obesity epidemic to describe this phenomenon. Not only adult but also young children and adolescents are affected, putting these populations at risk for obesity-related comorbidities, including sleep apnea, hypertension, and type II diabetes. Many hypotheses have been proposed to explain the increasing rate of obesity, including both biological

and environmental factors. Although larger portions, readily available food, and lack of activity all contribute to weight gain, the perception of a stressful environment is often raised by patients, both adults and children, as a major reason for overeating and weight gain. The term stress eating, also called emotional eating, has been used to describe eating behavior in which an individual responds to a mentally stressful situation with uncontrolled eating of high-calorie foods, even in the absence of hunger.

Stress can be loosely defined as a physical or emotional response by which the organism attempts to protect itself. A stressor, whether environmental (exogenous) or biological (endogenous), can cause certain physiological changes to occur. These changes, both biochemical and hormonal, permit an organism to adapt in survival mode. The adrenal hormones epinephrine, norepinephrine, and cortisol modulate the metabolic stress response in animals. During this fight-or-flight reaction, these hormones modify blood flow by increasing circulation to the heart, lungs, and skeletal muscle to facilitate escape while decreasing circulation to nonessential areas, including the splanchnic vasculature supplying the gastrointestinal tract. This classic stress response is not compatible with eating.

However, excessive cortisol secretion alone seems to stimulate appetite in certain individuals and has been shown to be a factor in visceral and abdominal fat distribution in humans. This is illustrated in the extreme in (1) Cushing's syndrome and Cushing's disease, disorders that both involve an overproduction of cortisol by the adrenal glands, and (2) people receiving high-dose corticosteroid therapy. Because of this pattern of appetite increase and fat deposition, some investigators have postulated that stress in animals (including humans) causes high cortisol levels, which, in turn, lead to stress-eating responses. Data supporting this hypothesis have been inconsistent, which is not surprising given the complexity of hypothalamic and gut signaling of hunger and fullness control, as well as the newly discovered role of adipocytes in appetite regulation.

In this article, we summarize the most recent research on stress eating in animal models and in humans. We also discuss environmental and psychosocial factors contributing to overeating and weight gain. Our clinical experience serves as a resource to identify practical strategies for the clinical management of stress eating in overweight and obese patients.

Biological Basis of Stress Eating

Current medical literature is replete with articles on both the psychological and physiological responses to stress. The animal literature typically exposes animals to noxious stimuli (including isolation, tail pinch, electric shock, cold water immersion) and examines food consumption. The results of these studies have been diverse. Following the stressors, both eating response and the weight of subjects have been variable, either increasing or decreasing compared to controls. A recent series of studies in rats using restraint as a stressor measured caloric intake, caloric efficiency, body weight, intra-abdominal fat, and hormonal levels including adrenocorticotrophic hormone (ACTH), insulin, and leptin. The results indicated that, although weight tended to vary after stress, the deposit of abdominal fat and the consumption of comfort foods (lard and sucrose-sweetened beverages) in proportion to chow increased. The authors suggested that the ingestion of comfort foods appeared to decrease stress hormone responses. They further speculated that the same type of response might occur in humans.

Human studies have typically addressed the interaction of stress and overeating by examining the hypothalamic-pituitary-adrenal axis. In controlled laboratory studies, stress is induced with either physiological or environmental manipulations, and hormonal measurements and/or eating behavior are measured. A blunting of the usual adrenal cortisol response to the pituitary-stimulating hormone ACTH is often reported. Other studies have indicated that laboratory stressors produced increases in serum cortisol response that could be positively correlated with the increased consumption of sweet and high-fat foods.

The discordant conclusions of both the animal and human studies have prompted more questions than answers. Nonetheless, there is general acknowledgment that stress-eating behavior exists and that it may pose a significant barrier to the treatment of obesity. If we are to treat obesity effectively, practical recommendations for treatment of stress eating are needed even before a complete understanding of the neurological and metabolic basis for this phenomenon is reached.

Practical Treatment of Stress Eating

A key element of stress eating is the consumption of food in the absence of physical hunger, often to the point of being uncomfortably full. Frequently, stress eating results in a sensation of uncomfortable fullness followed by feelings of guilt, self-hatred, and self-disgust.

The pattern of stress-related overeating is heterogeneous both among and within individuals and may

include constant grazing, binge-eating, and nighttime eating. During an episode of stress eating, significant quantities of comfort foods are consumed, uniformly described as palatable and most often sugar-fat or salty-fat combinations. Left untreated, regular stress eating may contribute to the obesity.

Following an incident of stress eating, an individual may attempt to compensate by consciously curtailing food intake. This restrained eating, in turn, may trigger more stress eating. Stress eating may be continuous over variable stretches of time or brief, depending on the intensity and duration of the stressor. Many environmental factors that increase anxiety may contribute to stress eating in both children and adults. These include frightening world events, financial worries, and occupational or domestic demands. Habitual exercise, which could help offset stress-eating through both regular calorie expenditure and stress reduction, is often avoided because of time constraints, concerns for personal safety, reductions in gym classes for youths, and increasing dependence for entertainment on more passive activities, such as television, computer and video games.

Despite the increased incidence of obesity, there remains the societal pressure to be thin. The quest for thinness at any cost abounds, but the ideal body type promoted in the media is not realistic for most people. A vicious cycle may occur when the failure of attempts at quick weight loss lowers an individual's self-esteem and increases frustration, inciting further episodes of stress eating. In order to break this cycle, active intervention is required. What is effective intervention? The health-care community must help refocus our society's expectations by helping the individual set realistic goals for achieving a healthy weight. People tend to do well when very small yet incremental behavioral changes are adopted initially. The goal of better health, not a specific weight, should be emphasized; as little as a 5% reduction in weight can improve health significantly. Motivational interviewing, a form of nonthreatening history-taking, enables the practitioner to identify unhealthful eating behaviors in a patient while simultaneously permitting a collaborative interaction in which the patient determines the course of action and the clinician serves as a facilitator. To best assist a patient, the health-care provider should become familiar with some basic behavioral modification techniques.

Overview of Lifestyle Change

Stress eating may be considered one of several types of nonhunger eating, that is, eating that is unrelated to physiological hunger. Rarely do stress-eaters complain of hunger symptoms (e.g., sweating, headache, poor

concentration, irritability, lightheadedness, racing pulse, and hypotension) prior to food consumption. In fact, most of these individuals acknowledge no feelings of hunger when feeling the urge to stress eat. Although there is no consensus about treatment, the National Weight Control Registry has been tracking a cohort of 3000 individuals who have lost at least 30 pounds and kept it off for at least 1 year. Started in 1994, the Registry has identified five behaviors contributing to long-term weight loss: (1) maintaining high levels of physical activity; (2) following a low-fat, low-calorie high-carbohydrate diet; (3) monitoring food intake and weight; (4) possessing coping skills enabling the continuation of weight-loss strategies despite stressful situations or cravings; and (5) eating breakfast. Although it is not known whether these recommendations will help for stress eating by itself, it is reasonable to use these tools to manage weight over the long term.

Overcoming Therapeutic Barriers

Many health-care professionals, even when provided with materials, do not discuss weight control with their patients. The reasons for this are unclear, but there are probably at least two: (1) The discussion of lifestyle change is time-consuming and cannot easily be accommodated by the typical 10- to 20-min patient visit and (2) clinicians may hesitate to broach the subject of weight because many of them are overweight or obese themselves, they are afraid they might insult the patient, and they may feel incompetent to discuss weight management because the medical education curricula today generally do not incorporate courses related to weight control. Nonetheless, it is quite possible to include brief patient education sessions about weight management into a primary-care office visit, especially in the context of a longitudinal clinician-patient relationship. For a clinician who cannot or will not spend time on this topic during the office visit, important weight management concepts can be assimilated into patient handouts that can be distributed without discussion or left in the examination and waiting rooms for patients to peruse at their leisure. In addition, the use of a physician-extender can be considered to help guide the weight-loss process.

Use of the Prescription Pad

The clinician's role as medical expert and prescriber of treatment can be a powerful catalyst of change. Patients are likely to take a written prescription more seriously than other modes of medical advice, including verbal instruction and guidance. The use of the prescription pad for dietary and exercise recommendations can be a very useful tool because it lends

further credibility to lifestyle change as an actual treatment recommendation. (When necessary, more traditional prescriptions for laboratory testing, weight-loss medications, and/or a surgical consultation can be added.) Moreover, the patient is more likely to remember what has been written down, particularly if there are multiple instructions.

Basic Recommendations for the Primary-Care Clinician

Recommendations, such "eat less; exercise more," although logical, are unhelpful because they are both condescending and too general. The majority of obese individuals are well aware that in order to lose weight, they must eat less and exercise more; however, they do not know how to accomplish this. Therefore, the clinician's suggestions should be specific and individualized.

A clinician can first teach a patient to become more cognizant of the physical signs of hunger and satiety by making the following suggestions.

1. Use a three-point hunger scale to rate feelings of hunger (1 = hungry; 2 = content; 3 = stuffed).
2. Determine when the desire to eat coincides with higher stress levels, with signs of physical hunger, or both.
3. Attempt to delay eating during high levels of stress, particularly if no physical hunger is sensed.
4. Eat slowly – it takes 20 min for the stomach to signal fullness to the brain.
5. After a 100- to 200-Cal snack, find a distraction to help postpone further eating for at least 1 h (encourage noneating, stress-reducing activities).
6. Repeat the phrase, "I can always have more later"; this can reassure an individual who becomes anxious if food is unavailable.
7. Avoid liquid calories; this is a crucial piece of advice because patients often ignore beverages in their calculations of daily calories consumed.

A sense of deprivation often occurs when people eliminate favorite foods from their daily diet. Historically, such foods have been judgmentally referred to as illegal, off-limits, not allowed, and even bad. The avoidance of these foods, in and of itself, can cause mental stress while the forbidden nature of these foods may increase their desirability and thus provide a powerful trigger for stress eating. The uncontrolled eating of allowed foods is a common way to overcompensate for not being permitted to eat the desired food, but this most often results in an overconsumption of total daily calories because the mental hunger has not been fulfilled. Instead, stress-eaters should be given permission to eat their favorite foods in the context of a healthful diet. If no foods

are excluded from stress-eaters' diets, compensatory overeating is more likely to be better managed. A caloric allowance for favorite foods should be considered in a day's food intake equation.

Nearly all patients are well aware that insufficient physical activity presents a significant barrier to weight control. Regular physical activity, because it can relieve stress, helps to reduce the need to stress eat. Activity also modestly increases the expenditure of calories, making long-term weight loss success more likely. After medical clearance, the exercise prescription for all sedentary individuals should emphasize a gradual increase in duration and intensity of activity. For sedentary individuals reluctant or unable to exercise, increasing the activities of daily living can provide an alternate route for augmenting calorie expenditure. Activity goal-setting can be accomplished with the use of a pedometer, a small digital instrument which, when clipped to an individual's waistband, records the number of steps taken per day. By demonstrating that simple changes can make a significant difference in overall activity level, a pedometer can also be a motivational tool. The daily step number may be increased with such modifications as parking farther away from work or the store, choosing a more distant bus stop, taking the stairs instead of the elevator, using the manual channel-changer instead of the remote, pacing while talking on the phone, and walking for 5 min during a lunch break.

Other Behavioral Techniques

Many weight management programs, whether commercial or medical center-based, apply the principles of cognitive-behavioral therapy directed at lifestyle change. In the case of lifestyle change related to weight control, these principles can help people strike a more healthful balance in their behaviors relating to both eating and activity. These include self-monitoring, bartering, cognitive restructuring, preplanning, positive self-talking, imaging, and asserting.

- Self-monitoring, one of the most important tools for the stress-eater, has been proven to lead to sustained success. The technique involves recording periodic (i.e., daily or weekly) weights, daily activity, and food intake. Despite the proven efficacy and relative ease of this method, many individuals seem to have difficulty sustaining the effort involved in logging.

- Bartering in behavioral modification terms means making choices. Substitutions, trade-offs, and banking calories are different types of bartering.

- Cognitive restructuring is a technique that allows replacing eating and rumination about food with

another behavior. As a cognitive-restructuring exercise, the patient may generate a list of stress-reducing activities. Such activities might include taking a bubble bath, talking to a friend, watching a movie, reading, getting a massage, participating in community or other volunteer work, becoming occupied with a hobby, taking a class, cleaning out drawers, shopping, or rekindling intimacy with a partner.

- Preplanning is a method of preparing for events in which stress eating is likely to occur. Through this process, many patients have been able to retrieve a sense of control over their eating.

- Positive self-talk is another effective way to interrupt the stress-eating pattern. Negative thoughts seem to exacerbate stress eating and should be discouraged; the switch to a more affirmative cognitive process often takes practice. One exercise incorporates patients' transcribing negative thoughts in one column and positive replacement statements in an adjacent column. A variation on this method is for patients to speak aloud or write down all their accomplishments, recent or past, or to congratulate themselves on accomplishments related to weight loss, for example, to say "I am a size smaller than I was 2 months ago" or "I rode the stationary bike for half an hour three times this week." Repeating these sorts of sentences may not only change the patients' thought processes but also help relieve stress, both of which will subsequently promote behavior change.

- Imaging is mental rehearsal. By envisioning an upcoming stressful scenario, individuals may also imagine an appropriate response to the stressor that can later be put into action. Another strategy is to recommend imagining a relaxing situation (e.g., lying on a beach or getting a massage) during a stressful event, a process that, through mitigating the feelings that induce stress eating, may minimize the odds of an actual stress-eating response.

- Asserting is an invaluable tool for the stress-eater. Because individuals stress eat in order to avoid confrontation, teaching strategies to gradually increase self-assertiveness are important. The phrase "I need" is central to learning self-assertiveness. For example, people can be given the homework of becoming assertive in a relatively nonthreatening situation, such as informing a demanding young child, "I need to go take a shower now, and I need privacy while I am doing this."

Understanding and Addressing Failure in a Stress-Eater

The breaking of any unhealthful habit (or addiction) carries with it the risks of lapse, relapse, and collapse.

In fact, when the habit is ingrained, lapses are almost inevitable and should be considered a normal part of the habit-changing process.

A lapse is an isolated episode of recurrence of the old habit or behavior. Lapses often occur when people have not planned for an unusual occasion, but they can happen even with the most detailed calculation. A relapse is several episodes in succession of the old pattern of behavior. Vacation commonly provokes a relapse, which, for some, is difficult to reverse. Collapse, a complete abandonment of healthful behaviors, is less likely if the stress-eater, after a single lapse, is able to get right back on the track of a palatable and manageable weight-loss plan. In the event of a lapse or relapse, the stress-eater should be encouraged to bring all behavioral methods to bear, return for weight management visits in order to get the necessary reinforcement, and garner support from friends and family.

Other Therapies: Pharmacotherapy and Surgery

Weight-loss medication should be considered a tool to make the lifestyle effort easier. It is not a replacement for lifestyle, nor should it be viewed as a cure for obesity. Some prescription medications can be used in stress-eaters who exhibit great difficulty with behavior change related to eating and activity. Medications such as sibutramine and bupropion (in depressed obese patients) exert more subtle effects on hunger and satiety and can therefore be employed as teaching devices. However, even with the medications, the signals can be ignored and an individual can eat through the effects of the medications. Therefore, the importance of a complete explanation by the practitioner about the use of these or other weight-loss medications cannot be overemphasized. Sibutramine is approved for long-term use in weight loss, and although active weight loss seems to last for approximately 6–9 months for responders, the weight maintenance effects of the drug may continue for at least 2 years. Bupropion, which is FDA-approved as an antidepressant and as a smoking-cessation adjunct – and not FDA-approved for weight loss – has sometimes been used for weight management in depressed patients. Sibutramine, used either intermittently or continuously, can help promote both weight loss and maintenance. Another medication, orlistat, a pancreatic lipase inhibitor, also has behavioral effects, but not by acting directly on the brain; this medication works by inhibiting the absorption of dietary fat from the intestine. When orlistat is taken as directed and a high-fat meal is consumed, bloating, diarrhea, flatulence, and leakage of foul-smelling stools will occur as a consequence of the decreased dietary fat absorption. The medication allows weight loss in part due

to a reduction in the absorption of calories but primarily via its role as a negative reinforcer because the consumption of high-fat comfort foods results in unpleasant side effects. Because this medication has no effect on carbohydrate or protein absorption, total calorie intake may not be reduced.

Bariatric surgery, including both the roux-en-y gastric bypass and laparoscopic gastric banding, is initially considered by many patients to be the cure for obesity. When a severely obese individual (BMI 40 or greater) has been unable to maintain weight loss even with sustained effort, weight loss surgery should be considered. For these patients, either restriction (gastric banding) or a combination of restriction and malabsorption (gastric bypass) can be the missing tool in the weight management toolbox. Obesity surgery allows the motivated patient to sustain a lifestyle effort that results in long-term weight-loss success. The lifestyle after surgery is quite demanding, and patients need to be taught that even after surgery it is possible to regain weight with poor eating habits – including grazing throughout the day and consuming high-calorie liquids. The stress-eater must be taught new behavioral modification techniques to manage stress without food, with these concepts being reinforced after surgery for at least 2–3 years.

Conclusion

Stress can produce both biochemical and behavioral responses in certain individuals, often resulting in stress eating and subsequent weight gain. Stress eating may be an important contributor to the current obesity epidemic. Although the understanding of stress eating is rudimentary at this time, certain behavioral techniques seem to be effective treatments, at least for some patients; many of these therapies are outlined in this article. These strategies can be easily initiated by a wide range of health-care providers during routine outpatient office visits and need not be time-consuming. Although all patients will not respond, many patients will benefit from a brief review of treatment options.

Changing eating behavior is difficult, but it is possible when a stress-eater is motivated to change and is willing to put in the effort. Assistance from health-care providers may facilitate lifestyle changes sufficient for many patients to achieve long-term weight-loss success. A basic understanding of simple behavioral modification will allow a more effective treatment of obesity in the primary-care setting. In certain individuals who are refractory to such methods alone, referral to a comprehensive weight management program may be necessary, particularly for the coordination of the more complex modalities

of cognitive-behavioral methods, diet and exercise education, and the judicious use of medications and surgery.

Treatment

Glossary

- Disaster* Natural calamities such as floods, earthquakes, and fires; also human-made calamities and other traumatic situations.
- Disaster phases* Time periods around disasters. These are (1) preimpact, the period before the disaster; (2) impact, when the disaster occurs; (3) recoil, the period immediately after impact; (4) postimpact, the

period days to weeks after impact; and (5) recovery and reconstruction, the period months or years after impact.

Biopsychosocial templates that evolved to enhance survival in specific circumstances. Examples are fight, flight, adaptation, and attachment.

An experience in which a person's life is grossly threatened and from which a variety biological, psychological, and social wounds and scars result.

External situations in which trauma occurs.

Survival strategies

Trauma

Traumatic situations

Features of Disaster Syndrome

Wallace described the responses of Petun warriors who in 1649 returned to their village to find their kin had all been slain or captured. They sat down in the snow, mute, and no one stirred or spoke for half a day. Wallace noted that such responses are ubiquitously found in disasters and are variably described as shock, stupor, and being dazed, stunned, and numbed. He added that, as well as sitting, victims may stand motionless or wander aimlessly. Emotion

such as pain, grief, fear, and anger are missing, and people are docile. The state may last up to hours or even days, injured people remaining dazed longer. The features of disaster syndrome are opposite to the anger and fear (fight and flight) sympathetic nervous system-associated arousal in posttraumatic stress disorder (PTSD) and some other anxiety disorders. This suggests that there may be a variety of emotional and biochemical survival responses in trauma that can develop into a variety of later symptoms.

The Place of Disaster Syndrome in Disasters and among Similar Syndromes

The behavioral features of disaster syndrome described by Wallace are still valid in descriptions today and are called by the original name. However, various psychological, behavioral, and physiological lines of research emphasize different aspects of what is behaviorally disaster syndrome and call them by different names. The psychological equivalent has been called psychic shock and the physiological equivalent general adaptation syndrome; conservation-withdrawal syndrome spans the all biopsychosocial aspects.

Psychic Shock

Psychic shock is the subjective view of being stunned. It has been most studied in bereavement and dying and is seen there as the first stage of the grieving process.

Subjective feelings of psychic shock as a response to being told the news of someone's death use physical metaphors such as an assault, a blow on the face, head or the guts, being knocked out, or winded. Psychological terms include being overwhelmed, not being able to take it, the world shattering around one, and sinking into a black hole.

Defenses against such sensations include denial voiced as disbelief and dissociation, described variably as feeling numb or as experiencing a sense of unreality of the world or of oneself. A common description is looking at oneself and the events as if they were a film.

General Adaptation Syndrome

Selye described general adaptation syndrome as a ubiquitous triad of physiological stress responses that were associated with psychic shock. The stress responses are the enlargement of the adrenal cortex and increased levels of cortisol; shrinking of the thymus gland, spleen, and lymphatic structures (along with compromising immunocompetence); and deep

ulcers in the stomach. Selye noted that these responses help organisms to adapt to overwhelming situations.

Conservation-Withdrawal Syndrome

Conservation-withdrawal syndrome, described by Engel and Schmale, enlarges on the features of disaster syndrome by emphasizing immobility, quiescence, and unresponsiveness, accompanied by sagging muscles, feelings of extreme fatigue, constricted attention, and detachment.

Adding to general adaptation syndrome, conservation-withdrawal is associated with parasympathetic, trophotropic activity, which may manifest in diminished heart rate to the point of arrhythmia and possibly asystole and even death. Gastric secretions have been noted to diminish, possibly because food intake does not occur in this state. The syndrome has been observed at all ages, ranging from neonates to adults, and in various situations in which no definite course of action was possible.

Sense and Purpose of Disaster and Associated Syndromes

Initially it may be difficult to see these responses of being overwhelmed as adaptive. However, just as physical shock helps survival, so may psychosocial shock. For instance, Darwin noted that immobility made animals less likely to be seen and be attacked and that the deathlike state could stimulate predators to release their grip. Immobility could also help others to scoop the unresisting person to safety and help members of the group to find its previously abandoned members. Further, the associated psychosocial limpness or docility may facilitate cooperation with helpers and their directions. Last, a type of psychological encystment and conservation of energy could provide a buffer space for the replenishment of reserves.

Selye and Engel and Schmale also saw their respective syndromes as primary regulatory organismic templates that enhanced the survival of the species. They were at the opposite end of the spectrum to fight and flight, and they occurred in situations in which fight and resistance could be fatal but in which rolling with the punches and surrendering old goals and finding new ones was advisable.

Valent integrated the biopsychosocial features and purposes of these syndromes into a survival strategy that he called adaptation. The strategy adapts the organism to situations requiring initial surrender, but through processes such as grieving it facilitates the organism's turning to new hopeful situations and bonds. If this does not occur, physiological symptoms, depression, and other illnesses can occur.

Unfolding of Disaster Phases and of Disaster Syndromes

The features of later disaster phases and the unfolding of the disaster syndromes (or the adaptation survival strategy) follow.

Ensuing Disaster Phases

In the postimpact phase (Wallace's stages 2 and 3) of disasters, survivors emerge from their cocoons. They are grateful to be alive, help others, and reconnect with family and friends. Survivors drop their usual reserves to become a cohesive altruistic community. The accompanying optimism has been called the post-disaster euphoria. At the same time, anger is often directed at outsiders whose help is seen as unempathic. In addition to Wallace's original stages are the recovery and reconstruction phases, hard prolonged times of rebuilding the physical environment and internal lives. The names, timing, and contents of the phases are flexible, indicating fluctuating progression.

Similar phases occur in other traumatic situations, although different contents are emphasized in the literature. For instance, in bereavement psychological features are emphasized. After shock come the phases of searching, then anger, guilt, and working through, followed by acceptance and turning to new bonds.

Unfolding of Disaster Syndrome

Physiological stress response derivatives of disaster syndrome (or adaptation survival strategy) may manifest clinically as hypotension, dizziness, tiredness, fatigue, and the sense of being ill. Prolonged compromised immunocompetence may help to account for the increased rates of infections, autoimmune diseases, and cancers following disasters, bereavements, and other traumas. Thus, this specific response may be

significantly involved in the frequent stress-induced maladies. Maladaptive psychological unfolding includes hopelessness, despair, giving in, unresolved and chronic grief, and clinical depression.

Treatment

The treatment of psychic shock, like physical shock, includes physical and psychological warmth, comfort, and support. Physical contact with another human, a reassuring voice, explanations of what is happening, hope, and connection with loved ones are helpful. Later treatment depends on the nature of the evolving symptoms and illnesses. The best treatment is prevention or mitigation of circumstances in which people are overwhelmed.

Disaster Stressors

Stressor Elements and Psychosocial Effects

Vulnerabilities and Special Populations

Determining Who Is Affected

Recovery Environment

Glossary

<i>Disasters</i>	A class of events that can overwhelm individuals and their communities. Disasters elicit biological, psychological, and social stress reactions in individuals and affect the functioning of a community's social systems.
<i>Disaster stressors</i>	A range of events experienced by individuals in the course of their exposure to a disastrous situation. Disaster stressors may occur prior to, during, and in the aftermath of the disaster. The impact of these stressors is mediated by factors such as individuals' perceptions of their role in the disaster and the community's awareness of its scope.
<i>Mass violence</i>	A range of actions intended to injure, kill, or terrorize groups or communities. These may range from individual impulsive acts to group or community-based actions calculated to promote fear, civil disruption, or cultural-political change.

Disasters, by definition, are overwhelming events both for the communities they affect and for the individuals involved. The stress associated with disasters affects the functioning of social systems as well as creating biological, psychological, and social reactions in the people affected. As an event, a disaster may be brief or long lasting, anticipated or unexpected, humanmade or the result of natural forces, or any combination of these. Such elements, as well as background strengths and vulnerabilities, may contribute to how the events are resolved and to the outcomes: positive or adverse.

A range of models have been considered in describing disaster response. These include those based on

linear, systemwide reactive processes. A phase model, for example, may include warning, threat, impact, inventory, rescue, and recovery. This is one relatively simple model for a single-incident disaster. Both individual and social system reactions may be relevant in each phase. There is also a range of person–environment interactive models, which conceptualize the way that individuals and groups process the features of the event and their own capacities in their response to disaster events.

There is recognition that disaster scenarios are increasingly complicated by political, cultural, and military factors. A number of authors have outlined ways of conceptualizing and planning responses to these complex emergencies. Modern disaster planning, it is argued, must encompass the multiple and compounding disasters of famine, conflict, social disintegration, and the degradation of the environment. These scenarios more often reflect experiences within developing countries and cannot be easily conceptualized within the usual frameworks.

Disaster Stressors

The stresses experienced by individuals depend not only on the objective nature of the disaster event itself but also on the previous experience, perceived coping, available resources, and response readiness of those affected. For instance, a hurricane or flood may have been anticipated through recent warnings. Similar previous events may have prompted the creation of effective early warning and response systems. Alternatively, these natural occurrences may be totally unexpected, affecting particularly vulnerable human habitats with few counter-disaster systems in place. This latter scenario was seen in several regions, with devastating consequences, following the Indian Ocean earthquake and tsunami in December 2004. This interplay of factors means that those involved may experience effects ranging from the destruction of their homes, families, or communities to involvement in an exciting and unique challenge that has been successfully overcome.

The type of disaster, its intensity, and the availability of response resources may all be significant mediators of the psychosocial response. It has been generally observed that, as the level of exposure to disaster-related stressors increases, the mental health symptoms of those exposed similarly increase. This increase in impact associated with proximity, duration, or frequency of exposure is commonly referred to as the dose–response effect and has been observed across

different types of disasters and other traumatizing events.

Adverse impacts on mental health are possibly the most prevalent consequence of disasters. In a broad review of 121 studies examining disaster mental health, Norris found that adverse disaster effects included, in order of frequency, specific psychological problems (notably posttraumatic stress disorder, PTSD; major depression; and generalized anxiety disorder), nonspecific distress, physical health problems, chronic problems of living, resource loss, and problems specific to youth. The most common specific disaster stressors include bereavement, life threat and injury to self or family members, horror, property damage, and financial loss.

Disasters involving mass violence are found to consistently produce higher levels of distress and psychological impairment. Terrorism with conventional weapons typically produces immediate health effects in the form of injuries and deaths. For the perpetrators, these effects may be incidental to the wider aim of creating cultural or political change through civil disruption. In this sense, the intended effects of terrorism, as the term implies, are primarily psychological – to foster pervasive insecurity through specific acts of violence, create behavior changes disruptive to public infrastructure, and engender a loss of confidence in public institutions. Terrorism involving biological, chemical, or radiological (BCR) agents represents a particularly insidious, ongoing form of assault. Biological agents, for example, are typically invisible and odorless, produce delayed illness (and uncertainty), and may be associated with grotesque forms of death.

In one of the broadest reviews of the disaster literature to date (225 studies), Norris observed that when other variables are controlled, those exposed to mass violence and terrorism experience severe impairment at almost twice the rate of those subjected to natural or technological disasters. Acts defined as mass violence range from incidents such as the Columbine High School shootings to the September 11 attacks and the London underground bombings of 2005. Technological disasters are associated with human failure or negligence and may include pilot error or the industrial accident and chemical release at the Union Carbide factory in Bhopal, India. In general, the review findings indicated that those who experience technological disasters do not experience greater distress or morbidity than those exposed to natural disasters.

Disasters that are the direct result of human malevolence may be particularly difficult for survivors to comprehend and assimilate and may increase the likelihood of intrusion symptoms. In contrast, the

perceived absence of malevolent intent associated with natural disasters and technological accidents may allow the resolution of these events to occur more readily. An exception to this may be those humanmade disasters associated with chronic and invisible threats, such as nuclear radiation and toxic waste. Distress may be further heightened by supposed mismanagement or neglect, which allowed the exposure to occur. Cycles of blame may ensue. The actual and perceived risks may include damage to health, children, genetic/reproductive health, and otherwise unknown effects. These events often generate a different pattern of response characterized by chronic stress and associated physical health problems rather than discrete mental health conditions.

Location and the availability of economic resources may also be significant predictors of stress and other mental health effects. Natural disasters in developing countries have more severe consequences than either natural or technological disasters in developed countries. This is largely due to a combination of more severe natural events and a limited resource base, including poor housing and warning/recovery systems. It has been observed that following a disaster, individuals from developing countries experience severe mental health outcomes at more than twice the rate of those from developed countries.

Although multiple classifications of disaster have been attempted, they do not provide an easy guide to their consequences or to the appropriate actions to deal with the stress or mental health effects they may generate.

Stressor Elements and Psychosocial Effects

Life Threat and Traumatic Injury

Methodological inconsistencies make it difficult to determine, in comparative terms, which elements of disaster stressors have the greatest psychosocial impacts. Debate has ensued in the literature about which disaster exposures are more pathogenic (i.e., produce greater psychiatric morbidity). Despite these inconsistencies, the more comprehensive studies have generally found that threats to life and injury during disaster have stronger or longer-lasting effects on mental health.

Individuals who experience threat to their lives, especially when this is associated with shock and helplessness, are at increased risk of a range of reactive processes. These include heightened arousal, numbing of emotions, avoidance behavior, and the reexperiencing of traumatic events. Intense arousal and distress may trigger specific psychological and

physiological reactions, including dissociation or heightened arousal with prolonged elevation in heart rate. It has been shown that these reactions are more likely to develop into a pattern of psychiatric morbidity such as acute stress disorder (ASD), PTSD, or other specific conditions such as depression and generalized anxiety disorder. Studies of disasters such as the Mount St. Helen volcanic eruption have shown the specificity of perceived life threat as a stressor associated with the development of PTSD in adults. Pynoos et al. observed a similar relationship with children affected by a sniper shooting at a school.

Trauma events occasioning physical injury are also associated with greater mental health impacts. Ten years after the 1988 Piper Alpha oil platform disaster (in Scotland), 21% of workers directly exposed still met stringent criteria for PTSD, with features such as physical injury and survivor guilt associated with significantly higher morbidity. Consistent with other dose-response effects, the extent of the mental health impact also appears to increase with the severity of the injury. This phenomenon has also been observed in adolescents injured during a massive industrial accident in Toulouse, Italy. Injury effects also appeared to be cumulative, with PTSD rates being even higher in those with injury to family members and personal injury. However, the broad findings in relation to injury have been questioned. O'Donnell et al. critically reviewed the traumatic injury literature and suggested that methodological discrepancies and confounds in this field must be resolved if mental health associations are to be more accurately determined.

When deaths are massive and gruesome, the levels of PTSD-related morbidity may be considerably higher, particularly for those who may have experienced dissociation in relation to this experience. Lifton described the phenomena of death immersion (when the levels of death are massive and horrific), as occurred in Hiroshima. Unfortunately, genocides in modern conflict, war, and mass killings can also provoke such an effect. Massive deaths, or the deaths of key figures, may threaten the functioning of the community and its survival. This was exemplified in the 1966 disaster where a slagheap destroyed the school at Aberfan (in Wales). Although some of the effects of this tragedy have been long-lasting, the community did indeed survive and renewed itself. Death counts may provide an indicator of the degree to which a community may be affected by a disaster, but they are not the only stressor effect.

It must be remembered that, for the majority of individuals, reactive phenomena of the type noted normally diminish over time. Residents of lower Manhattan, for example, reported significant acute

mental health effects immediately after the September 11 attacks (measured as rates of PTSD and depression), followed by a pattern of strong recovery within 4 months. At a population level, there is a consistent trend for most survivors to return to their predisaster mental health status within several months. This occurs across disaster types, but it is rarely a linear decline.

Losses

Personal losses Personal losses may range from the intense and personal loss of a primary attachment figure (a parent, child or partner) to the loss of other family members, friends, and neighbors. Losses may extend to the deaths of community members and leaders, affecting the sense of community structure and leadership, key resources on which both an ongoing sense of security and practical recovery management may be based.

When personal losses relate to the deaths of others, bereavement represents the normal reactive psychological process for those dealing with these disaster outcomes. Grief and mourning occur for those to whom the individuals were attached or for whom they cared or valued. There is often an initial period of disbelief, which may be more pronounced when the death is unexpected and untimely. This is especially the case in the midst of the chaos and threat frequently observed in a major disaster. This shock, denial, and sense that things are unreal may affect whole communities as well as individuals. Although bereavement represents a normal reaction to traumatic loss, some individuals may be at increased risk of complex grief and other morbidity in the longer term. Risk factors for this may include a belief in survivor responsibility, the nature of the loss (e.g., sudden losses or the death of a child), and anxious personal coping styles.

The nature of disasters and some terrorist attacks is such that there may be prolonged periods of uncertainty about the fate of loved ones. The remains of some of the deceased may never be located. Others may be grossly disfigured and identifiable only through forensic examination. In these instances formal disaster victim identification (DVI) procedures are used, such as DNA and dental record analysis. Evidence gathering for criminal investigation may also be required. Although providing certainty and supporting a process of justice, the delay and apparent complexity of these procedures is often intensely stressful for those who are bereaved. Raphael, Dunsmore and Wooding described the complex DVI and support processes following the terrorist bombing on the Indonesian Island of Bali in 2002. They

described key support processes during this period, including viewings of the deceased, which may prevent or reduce negative mental health effects. They argued that it is not always apparent who the affected groups may be and that further research is needed to determine optimal methods of outreach and clinical support at such times.

Grief processes may be complicated by co-occurring experiences of personal life threat and traumatic stress reactions that may occur during disasters. Grief and trauma are distinct phenomena, the former characterized by distress, yearning, and an orientation toward the absent person and the latter characterized by heightened fear and arousal, vigilance, and a reactive orientation away from the feared event or its reminders. Galea et al. noted the specificity of responses to the September 11 attacks, stating that “experiences involving exposure to the attacks [and perceived life threat] predicted current PTSD and that loss as a result of the attack predicted current depression” (2002: 346). Similar specificity of response has been observed with natural disaster exposures.

Whereas grief, depression, and PTSD do represent distinct processes, losses during disasters or single-incident events (e.g., a motor vehicle accident) may result in co-occurring grief and trauma. These events cut across the ambivalence of everyday life and may particularly impact those in very dependent relationships, leading to patterns of complicated grief. The traumatic circumstances of disaster-related deaths often produces a complex mix of traumatic stress and bereavement phenomenology, which is more properly called a traumatic bereavement or traumatic grief. It remains unclear whether deaths resulting from particularly horrific exposures (e.g., the September 11 attacks) produce unique complications beyond traumatic bereavement or PTSD as they are currently conceptualized. However, the wider literature on complicated grief (traumatic and nontraumatic loss) indicates that certain groups may experience greater vulnerability. For example, the loss of a close family member (e.g., a parent, child, or spouse) is the best predictor of complicated grief. Preloss dependent or ambivalent relationship styles are also associated with enhanced risk. Early life experiences such as abuse or parental loss may similarly increase risk, possibly by promoting insecure attachment styles. Subsequent disaster losses may then exacerbate abandonment fears and affect mood regulation, increasing the risk of complicated grief.

The death of a loved one through acts of human malevolence, such as terrorism, has been shown to produce higher levels psychological morbidity than other types disaster. The arbitrary and calculated nature of these losses may be difficult for survivors

to comprehend and are associated with higher levels of intrusion and avoidance symptoms. There is anecdotal evidence that such events may also act as a significant and complicating stressor for those bereaved. Preoccupation with the reasons for the death (i.e., its meaning), the perpetrators’ motivation, and thoughts of revenge and justice may all act as a defense against the trauma. These preoccupations may ultimately inhibit acceptance of the loss and impede its resolution.

Clinicians working with populations so affected increasingly recognize the need to deal separately and specifically with the effects of both sets of stressor reactions to facilitate resolution. Traumatic stress effects (i.e., those related to life threat) must often be dealt with first, before it is possible to grieve. Regehr and Sussman suggested that an integrated evidence-based approach is likely to entail (1) cognitive restructuring and management of the arousal, avoidance, and reexperiencing of symptoms associated with trauma stressors and (2) phased (or parallel) relational therapies that resolve relationship issues and enable a new sense of the relationship and the self.

Community and resource losses In addition to personal losses of life, homes, and treasured possessions (e.g., family photographs), disasters frequently entail the loss of workplaces, neighborhoods, and community networks. Sociologists such as Erickson have studied these community impacts. Erickson described a massive flood affecting a mining valley and showed that there were not only the types of stressful experiences already but also the disruption of neighborhoods and social networks when people were displaced to new locations of safety and shelter. Although community losses may produce modest effects in themselves, their additive effects may be significant. Phifer and Norris observed that flood survivors from the United States who fared most poorly were those who experienced both high personal loss and high community destruction.

Community losses may not only produce grief but also lead to ongoing deficits and disruptions. These may include the loss of family and social structure and also the loss of opportunities for income and meaningful work. The Conservation of Resources stress theory predicts that psychological stress occurs when there is a threat of resource loss, an actual resource loss, or the absence of a resource gain following an investment of resources. Resource types identified within this theory include objects (e.g., homes and furniture), energy (e.g., money and insurance coverage), conditions (e.g., marriages and work roles), and personal characteristics (e.g., self-esteem).

Several studies have indicated that resource loss is an important predictor of psychological distress following natural disasters. Freedy et. al. found that 4–7 months after the 1991 Sierra Madre Earthquake (in Los Angeles County) resource loss was a more significant predictor of psychological distress than perceived life threat, prior exposure to traumatic events, and other stressful events. In a cross-national study 1 month after Hurricane Georges (Caribbean and U.S. gulf coast, 1998), Sattler et al. found that psychological distress (as measured by ASD symptoms) was most strongly predicted by location, resource loss, and the availability of social support. Approximately 25% of respondents in Puerto Rico and the Dominican Republic reported distress levels consistent with ASD, whereas only 10% of those in the United States (Alabama) and the U.S. Virgin Islands were affected in this way. Rates of depression were also higher in the first two countries. Although countries differed in reported vulnerabilities, the personal characteristics component of resource loss accounted for the greatest symptom variance overall. Basic object loss (food, water, and money) was greatest in Puerto Rico. Condition loss (family and work relationships) and object loss (sentimental items, furniture, etc.) accounted for the greatest resource distress in the Dominican Republic and the U.S. regions, respectively.

The limited resource base, greater exposure, and poor perceived support of developing countries produce significant mental health burdens. However, these resource spirals (continuing and compounding loss of resources) may be arrested through practical actions of the disaster response. For example, recent United Nations programs involving the priority reopening of schools, local markets, and factories have actively countered the prolonged sense of despair that may affect some postdisaster communities.

Separation and Dislocation

As noted, there are many aspects of disaster that separate family members and dislocate people from their homes and communities. In the aftermath of disasters, intense distress and searching behaviors are common as affected individuals look for their loved ones, even placing their own lives at further risk to do so. Information as to their whereabouts and opportunities for reunion may be the only influences that will lessen these behaviors. It may be, of course, that loved ones have died and grief will supervene; being able to see the body of the loved one may be a very important factor in resolution of the loss.

Mutual support of those so affected may be important for resolution, as may be the support of the

community in recognition and commemoration, perhaps of the site or in ceremony or memorial. As well as helping to reestablish a supportive community network, these rituals may support the resolution of these experiences by helping to construct a sense of meaning about what has occurred. This psychological process, sometimes referred to as an individual or community narrative, has been shown to be associated with better adjustment to traumatic events.

Dislocation is a process that relates more specifically to the loss of homes and the move to shelter. It may involve repeated moves to new places of safety or places to live until a new home is found. These may be key stressors for communities affected by natural disasters, but may profoundly impact societies subjected to bombings and warfare. This is also one of the powerful stressors affecting refugees.

Unlike losses through death or injury, dislocation stressors appear to affect mental health and well-being at a later stage and often in more chronic ways. This was first observed in studies of the effects of a cyclone that devastated the northern Australian city of Darwin. Parker found that an initial rise of distress measured in a population of evacuees reflected a mortality or life-threat stress. A subsequent rise several months later reflected dislocation/relocation stressor effects. Other studies of those affected by this disaster have shown similar longer-term stress effects related to dislocation.

Chronic Stressors

Disaster responses in communities often follow predictable cycles. There is typically an initial honeymoon phase, when there is an enormous positive and often altruistic response by surrounding communities, nationally and even internationally. This is driven by a wish to undo, or to make right, what has happened. Usual social boundaries diminish and there are powerful affiliative tendencies at a local level. However, this lasts only for the first few days or weeks. Then the reality of what has happened, what it will take to recover, who will pay, and how long it will take creates a very different environment. Anger and scapegoating, chronic distress, and frustration may occur. Confrontation with bureaucracies that have returned to their predisaster levels of functioning is common. All these factors may mean that there is an environment of disillusionment. This may contribute further to the distress of individuals or may adversely influence the functioning of the community, leading to cynicism and disappointment.

Fortunately most communities, like individuals, build on their resources and resilience and recover. The experience of the catastrophe becomes part of a

history of mastery and moving on. This is not always the case, however, and tragically, for some communities, the stigma of a particular catastrophe may remain. The community becomes identified with the disaster and the disaster with the community, often in the most negative ways—for instance the Chernobyl nuclear incident or the Port Arthur massacre.

Some disaster stresses, by their nature, are chronic and ongoing. Slow disasters include drought and deforestation and may provide the preconditions for starvation and the dislocation of communities. As noted, these environmental effects may coincide with chronic civil or ethnic conflict or the dispossession associated with years spent in refugee camps. The degradation of the environment through industrial accidents or toxic waste disposal can produce similar chronic effects.

Chronic stress may affect physical health via the immune system, neuroendocrine response, altered health behaviors (e.g. alcohol abuse), or changed mood states. Four months after Hurricane Andrew (in the United States) Ironson et al. found evidence that survivors were experiencing altered physiological functioning, suggestive of stress-related immune system suppression. Severe disaster stressors have even been known to lead to sudden death, as has been demonstrated in a number of different studies of earthquakes.

Posttraumatic Growth

For some individuals, the process of dealing effectively with loss or psychological trauma may ultimately provide a growth experience and enhance their personal maturity and relationships. This is well exemplified in the contributions of Victor Frankel and other Holocaust survivors. More recently, there has been increasing interest and study of the phenomena of posttraumatic growth. Tedeschi and Calhoun reviewed models of these phenomena and suggest that the provision of sensitive support and the opportunity for disclosure following trauma or disaster may allow significant cognitive restructuring in relation to the event. The experience of surviving and overcoming trauma may promote the development of a coherent and reempowered self-identity. In effect, the disaster experience and response may become a vehicle through which powerful changes to personal and group narratives may occur.

Vulnerabilities and Special Populations

Previous Exposure

Previous exposure to specific disaster stressors is an important factor affecting individual and community

response. In some people, this has built their strength, enhancing their capacity to overcome the new threat while also inoculating them against its stress effects. Conversely, exposure may have the effect of sensitizing some individuals, leading to poorer coping with subsequent events. For some, vulnerabilities associated with unresolved trauma or grief may surface again, triggered by the current crisis. Although there may be opportunities to rework those earlier experiences, they are often not recognized. Experiences such as childhood sexual abuse or wartime suffering may not clearly link to a current disaster context but are known to represent significant risk factors for further trauma.

Communities that have been exposed in the past may develop a disaster subculture. This may influence how they respond to warnings and to the disaster itself. This subculture reflects a belief system about what will happen, what can be done, and what the outcomes may be. This may influence responses in either positive or negative ways, depending on the adaptability of the beliefs and their fit with the particular incident.

Displaced Persons

Other vulnerable populations may be those who are already dislocated from familiar settings, for instance, refugees, new immigrants, or minority groups. They may lose their papers, documents of identification. Their links to their new community may still be fragile. They may not have the language, knowledge, or understanding needed to respond to the incident. Alternatively, they may have integrated these events in terms of earlier experiences of threat. They may experience intense fears for their safety because the chaos of the disaster is similar to the chaos they have known. Those who have suffered oppression in their home country may be fearful of government or law enforcement officials and emergency service workers. Displaced persons have been identified as vulnerable groups in many disaster responses and may need special attention to facilitate their recovery.

People with a history of mental illness are also a group that is vulnerable to the effects of disasters. The stressors associated with disasters are commonly recognized as risk factors that may exacerbate a range of preexisting conditions. Following traumatic events, individuals with prior or ongoing psychiatric conditions are more likely to experience a relapse or an exacerbation of these conditions, as well as the development of other forms of psychopathology, including PTSD. In addition to the stress effects associated with common exposures, specific elements of the event and its aftermath may trigger key

vulnerabilities. For example, bereavement or the loss of a support network or job may result in a relapse of major depression. The intense activity and officialdom of the recovery may heighten paranoid ideation in those experiencing psychotic conditions.

Indigenous peoples may face particular difficulties. Their backgrounds may have already involved life threat through premature mortality and racist violence. Other losses may involve family disruptions, deaths, and loss of land, culture, identity, and meaning. Such losses may entail both literal and symbolic dislocation from place, tribe, or community. Socioeconomic, educational, and other disadvantages may all contribute further to this background of traumatization. Disaster stressors superimposed on this context further increase the likelihood of adverse outcomes for these individuals and communities.

Children

Children and young people may be vulnerable through separation or by seeing effects on parents. The stresses of life threat, loss, separation, and dislocation can impact not only their present well-being but also their psychological and social development. This has been well demonstrated by Terr's 1991 in-depth studies showing that the effects may appear in repetitive traumatic play and behavioral disruptions that are both aggressive and withdrawing. Pynoos et al. studied the effects of a school-based sniper attack and were able to show that the mental health effects reflected the nature of the stressor experiences each child faced. For instance, those who experienced life threat showed PTSD phenomena, whereas those who experienced bereavement showed phenomena of grief and later depression. Those who experienced separation from their siblings showed separation distress phenomena.

The effects may be delayed. McFarlane reported that disaster-affected children's pattern of morbidity at first appeared less than that of the broader community and was particularly good. This had the apparent effect of forming a buffer between the children and the effects of what had happened. Their distress appeared later in the first year after a forest fire disaster and was also linked to ongoing symptomatology in their parents. Other studies of children support these findings and emphasize the need to recognize both behavioral responses and developmental impact. The centrality of the family for children, and their affection and security needs, must also be recognized if these stressors are to be dealt with.

The school is key environment of care and development for children following disaster. Teachers who have themselves been stressed may not identify the

effects on children. Some behavioral reactions may appear only in the school setting. For example, trauma-related cognitive and behavioral effects may become manifest as disruptive behavior or poor learning. Some school-based interventions have been shown to lessen the risk of adverse outcomes. In a study by McDermott, children used a workbook to facilitate the processing of traumatic experiences related to a forest fire.

The Elderly

Older people have been frequently described as vulnerable to disaster stresses. As with other studies in the mental health field, no specific increase in psychosocial morbidity has been found among the elderly. There may even be a decrease in later years. There is no good evidence that the elderly run a greater risk of mental health morbidity, although the patterns may be different. It has been observed that older people experience higher arousal but lower intrusive (re-experiencing) symptoms than young adults similarly exposed and that maturity and general life experience may buffer the stress of disasters. However, the elderly are also more likely to die during disasters. This may be due to several factors including recognition of warnings, the physical attributes necessary for escape, and a greater acceptance of death. As such, there is a need to ensure that individuals who may be vulnerable in this way are encompassed in disaster-response planning.

Determining Who Is Affected

Determining those who are affected by a disaster may be difficult. The registration of victims provides a formal mechanism, and this is often the role of organizations such as the Red Cross or Red Crescent or of formal institutions such as police services. But this really describes only the direct victims. A number of researchers have developed classifications of the different levels of victimhood in disasters. In broad terms, these include those directly experiencing the incident (who are often described as primary victims), those who were not there but are profoundly affected (such as bereaved family members), and those formally involved in rescue and helping efforts. The last group also experiences exposure effects and may be seen as secondary or indirectly affected victims. The distinction between victim and helper and the roles inherent in these terms may present a dichotomy that is a problematic. Victim implies weak and helpless, whereas helper implies strong and powerful. However, there are numerous examples of disasters in which survivors (the authors' preferred term) were both

victims and helpers in the early stages. As such, this distinction does not reflect the practical fluidity of response or the shifting of roles and exposures that often occurs.

It is of importance scientifically that a dose-response effect, as previously noted, may be demonstrated for the levels of stressor experience. In a number of studies, this relationship has been observed with both the frequency of exposure and its intensity or closeness to the epicenter of the disaster incident. The excellent 1989 study by Weisaeth of a workforce affected by a paint factory explosion and fire clearly shows such a relationship. The highest levels of morbidity were found in those closest to the explosion, with lesser levels in those further away. Significantly, however, a lesser but significant effect was also observed in workers who were not on shift but who would have been directly impacted had they been. This vicarious traumatization is a compelling indicator that the adverse effects of disaster and trauma need not be limited to direct physical exposure to the event. They may be powerfully linked to its indirect exposures and losses, including appraisals associated with personal risk.

Affected individuals and communities may experience any combination of the stressors identified. These may occur against a backdrop of ongoing life difficulties or specific events, but may be attributed to the distress of the disaster experience. They may be affected, or even secondarily injured, by the failure of others to acknowledge their experience or their suffering. The perception that social support is available and offered may be a central factor in reducing both disaster-related stress and longer-term mental health effects. Studies of Hurricanes Hugo and Andrew found that the deterioration in perceived social support (deterioration path) was associated with adverse mental health effects. Conversely, high levels of received support (actual postdisaster help) in the aftermath (mobilization path) were able to reduce these negative perceptions and offset some of these adverse outcomes. Despite findings that those with the greatest direct losses are often most strongly affected, these findings indicate that tangible support may bolster resilience; both may act as significant mediators of recovery.

Recovery Environment

The recovery environment consists of those natural and introduced forces that may influence the adjustment of individuals and communities following their experience of disaster. These include the natural processes of resilience that are vital for survival and the various adaptations that may support these, such

as specific coping strategies, personal resources, and social interaction. The more positive recovery environments are those in which the experience is acknowledged and help is offered but in which the strengths of individuals and communities to overcome disaster effects are recognized and supported. This approach, which focuses recovery activities on community resources and participation, is now formally advocated by the World Health Organization (Sphere Project).

The response to disaster-affected people and communities is often intense, and there may be a convergence of those wishing to help, including those offering practical and medical aid, debriefing, and subsequently welfare assistance. The altruism driving this wish to help represents the best of human values. Unfortunately, in this convergence there may be an excess of offers by the unskilled or those who may in turn become victims themselves. Debriefing is frequently part of such a response; however there is no evidence that it is beneficial to either emergency workers or the wider population. Some controlled studies have even shown that debriefing (i.e., critical incident stress debriefing) led to slightly but significantly worse outcomes. It was on the basis of findings such as these that the recent U.S. Consensus Conference on Mass Violence recommended against its use with the general population.

Cognitive-behavioral interventions have been shown to be effective in the treatment of specific trauma and are likely to benefit those with established PTSD conditions following disasters. Psychological first aid is an important helping response that focuses on the provision of immediate safety, reunion with loved ones, shelter, and support and the triaging of mental health and other needs. This approach promotes the recognition of and response to a postevent hierarchy of need and is now internationally recognized. Focused counseling for traumatization or grief may also be of value, but this needs to be based on evidence of effective interventions and delivered by skilled and knowledgeable personnel. The aim of any intervention may be "first to do no harm."

Unfortunately there remains a shortage of systematic investigations of the effectiveness of interventions postdisaster. This is largely due to the chaos of these events and their aftermath, as well as the methodological and ethical constraints on research at such times. As with the direct response, a primary aim of disaster researchers should also be "to do no harm" to affected populations. Some beneficial effects have been found for systematic intervention in environments such as schools or in postdisaster outreach and support programs as part of a disaster mental health response. There is a pressing need for

integrated research to ensure that human resources and mobilized personnel contribute to common goals, are effective in enhancing social and health outcomes, and are powerful and positive forces of normal recovery.

Glossary

<i>Adrenocorticotrophic hormone (ACTH)</i>	Is known under its scientific term “corticotropin”. Regulates adrenal steroidogenesis, specifically glucocorticoid synthesis and cortisol release.
<i>Adaptive response</i>	Complex set of an organism’s reactions to reestablish homeostasis.
<i>Apoptosis</i>	Cell death initiated by several mechanism in a regulated process. It is also termed “programmed cell death.” Cells with this fate undergo a sequence of changes typical for this process.
<i>Arginine-vasopressin (AVP)</i>	Peptide hormone, which stimulates pituitary ACTH release
<i>Corticotropin-releasing hormone (CRH)</i>	Also termed “corticotropin-releasing factor” (CRF) or “corticoliberin.” Main regulator of ACTH.
<i>Homeostasis</i>	State of dynamic equilibrium.
<i>LC/NE system</i>	Locus ceruleus / norepinephrine system.
<i>Proopiomelanocortin (POMC)</i>	Polypeptide secreted by pituitary cells which is the basis for several hormones of the pituitary that are yielded by alternative processing, including corticotropin, melanocyte-stimulating hormones (MSH), and endorphins.

The continuation of life depends on the ability of an organism to maintain a state of dynamic equilibrium or homeostasis. Homeostasis is constantly disturbed by entropic forces, the stressors; the state of threatened homeostasis is called stress. A complex set of behavioral and physical reactions, the adaptive response, is employed by the organism to reestablish balanced physiological conditions. At the beginning of the twentieth century, Walter Cannon and Hans Selye developed these modern concepts of stress and discussed the relation between stress and disease. In antiquity, Hippocrates regarded health as the harmonious balance of the four key elements of life – water, fire, air, and earth – and defined states of imbalance among these elements as disease. He also described the adaptive response as the “healing power of nature.” (Chrousos et al.)

The actual term stress was originally adopted from physics by Hans Selye. In physics, it describes the resistance of a body to applied pressure, following Hook’s law of elasticity. An acting force may distort a body elastically in a linear fashion or, if applied excessively in quality, quantity, or time, may produce nonlinear deformations. Similarly, stress may be a transient and time-limited state, well balanced by the adaptive responses of the organism, whereas excessive and prolonged stress may alter the physiological and behavioral defense mechanisms, rendering them inefficient or deleterious.

Anatomy and Physiology of the Stress System

Structures that include components of a network of neural and endocrine responses that are activated adaptively during stress have been collectively called the stress system. On the cellular level, molecules such as the highly conserved heat shock proteins (hsp) are primitive key elements of the cellular stress response. They comprise several families of proteins that are found across species and are classified depending on their molecular size (kilodaltons) into hsp16–30, hsp60, hsp70, and hsp90. They have been shown to regulate cell and tissue homeostasis and to be protective when this is threatened by stressors.

The central components of the stress system are located in the hypothalamus and the brain stem, the phylogenetically oldest parts of the brain. These centers receive information inputs of internal and external origins and compute the appropriate responses, which are effected by two main pathways: the endocrine hypothalamic-pituitary-adrenal (HPA) axis and the neural systemic sympathetic-adrenomedullary (SA) and parasympathetic systems. Their central regulators and peripheral end products, corticotropin releasing hormone (CRH), glucocorticoids, and catecholamines, are key hormones in the reestablishment and maintenance of cardiovascular, metabolic, immune, and behavioral homeostasis.

The Hypothalamic-Pituitary-Adrenal Axis and Stress

CRH, the principal central regulator of the HPA axis, is mainly produced by parvocellular neurons of the hypothalamus in the paraventricular and parabrachial nuclei of the medulla and in the central nucleus of the amygdala. Its action on the pituitary gland is supported by arginine vasopressin (AVP), also secreted by parvocellular neurons of the paraventricular hypothalamic nuclei (PVN). CRH induces the production and secretion of adrenocorticotrophic hormone (ACTH) from the pituitary, a hormone whose main target is the cortex of the adrenal gland. The intracerebroventricular administration of CRH causes the activation of the stress system and behavioral patterns similar to those observed during stress.

The adrenal gland, as the end organ of the HPA axis, is subject to functional changes of the stress system. It responds quite rapidly to sustained stimulation with hypertrophy and hyperplasia, which can be monitored on the macroscopic, microscopic, ultrastructural, and molecular levels. Whereas in acute stress high blood concentrations of glucocorticoids and ACTH can be found, in chronic stress high levels of glucocorticoids and relatively low levels

of ACTH are frequently observed. This dissociation between the central activation of the HPA axis and adrenal cortex function represents an adaptation of the stress system whereby medullary input and hypertrophy-hyperplasia of the zona fasciculata of the adrenal cortex sustain elevated glucocorticoid secretion in the presence of low normal ACTH concentrations. In addition, although ACTH is a potent secretagogue for adrenal steroids, this peptide does not seem to mediate the hyperplasia of the adrenal cortex during stress. Other pituitary factors are under discussion, especially N-terminal fragments of proopiomelanocortin (POMC).

Glucocorticoids exert their pleiotropic effects through ubiquitously distributed intracellular receptors in almost all tissues of the body. In addition, they participate in their own regulation of secretion through a classic negative feedback mechanism by binding to high-affinity mineralocorticoid and low-affinity glucocorticoid receptors in the frontal cortex, amygdala, hippocampus, hypothalamus, and pituitary. Exposure to pathologically elevated levels of glucocorticoids causes neurons to slow down their metabolism, although these neurons may undergo death by apoptosis. Therefore, this loop of HPA axis regulation serves to terminate or suppress an excessive response of the stress system.

The Systemic Sympathetic-Adrenomedullary and Parasympathetic Systems

This axis originates from mostly norepinephrine cell groups of the locus ceruleus, medulla, and pons (LC/NE). Efferent projections of these neurons terminate throughout the brain and spinal cord as well as in the peripheral ganglia of the autonomic nervous system. Through a complex neural network, a wide spectrum of physiological functions can be controlled. These include cardiovascular tone, respiration, skeletal muscle and adipose tissue metabolic activity, and gastrointestinal function. The adrenal medulla is an effector organ of this system, supplying the systemic circulation with epinephrine and norepinephrine. These catecholamines also potentiate ACTH-stimulated cortisol production by the adrenocortical cells.

Coordination and Communication of Hypothalamic-Pituitary-Adrenal Axis and LC/NE System

The organization and implementation of a qualitatively and quantitatively appropriate stress response depends on the fine-tuning of both the regulatory centers of the stress system and the response of target organs. Indeed, a complex network of neurons, neuronal and hormonal factors, and other cell mediators is at interplay at each level of interactions. The secretion of CRH and central catecholamines is controlled

by the neurons of the frontal cortex, mesocortical/mesolimbic system, and the amygdala–hippocampus complex. Neuronal pathways that produce γ -aminobutyric acid (GABA), substance P, and β -endorphin inhibit CRH-producing neurons. CRH is not only responsible for the activation of the HPA axis but also for the stimulation of LC/NE neurons in the brain stem.

The adrenal gland unites the HPA and SA axes under a common capsule. A great degree of intermingling of cortical and medullary cells increases the area of contact between these systems. In addition to the stimulation through ACTH, ACTH-independent mechanisms seem to be involved in the adaptation to chronic stress. The stimulation of chromaffin cells leads to the potentiation of glucocorticoid secretion, whereas glucocorticoids enhance catecholamine production by medullary cells.

Interplay of the Stress System with Major Endocrine, Immune, and Other Systems

The activation of the stress system helps the organism to overcome the influence of stressors and, therefore, postpones all functions that may interfere with the chance of the individual to survive. The stress system stimulates the mesocorticolimbic system, influencing motivation and reward phenomena. The stress system also stimulates the amygdala and hippocampus. The former generates fear and anxiety, whereas the latter participates in the negative feedback control of the HPA axis; both recall implicit emotion-laden memories. Neurons of the arcuate nucleus of the hypothalamus produce POMC-derived peptides. Two of these, α -melanocyte-stimulating hormone (-MSH) and β -endorphin inhibit the activity of the stress system. Projections to the brain stem and spinal cord elevate the gain threshold, producing so-called stress-induced analgesia.

The activation of the stress system leads to the inhibition of a number of endocrine axes. These include the gonadal, growth, and thyroid axes. The direct inhibition of central neural circuits is supported by the peripheral suppressive actions of glucocorticoids.

Other profound consequences of stress system activation are observed in the immune system. However, the adrenal cells express toll-like receptors, making the adrenal cortex sensitive to registering the activations of the innate immune system. Further important participants in the immunological homeostasis are cytokine signals from cells of the immune tissue. All three major inflammatory cytokines – tumor necrosis factor α , interleukin 1, and interleukin 6 – produced at sites of inflammation in a cascade-like fashion, exert stimulatory effects on the HPA axis. Their actions are directed

to all three levels of the HPA axis. The most potent mediator among them is interleukin 6; it causes elevation of CRH, AVP, ACTH, and the glucocorticoids. Indirect actions of the inflammatory cytokines on the HPA axis are also attained through the stimulation of the noradrenergic centers in the brain stem. In chronic hypoactivation of the HPA axis, increased serum levels of interleukin 6 can be observed.

The stress system uses additional mechanisms to affect immune homeostasis. In addition to the suppressive effect of glucocorticoids on the production of tumor necrosis factor α , interleukin 1, and interleukin 6, the glucocorticoids also inhibit the target tissue responses to cytokines through the suppression of nuclear transcription factor- κ B and activator protein 1 (AP-1). Glucocorticoids also cause a switch from type 1 T-helper cytokine profile to type 2 T-helper cytokine profile by inhibiting interleukin 12 and by stimulating interleukin 10. In this way, a shift from a cellular to a humoral immune response is promoted. In addition, the glucocorticoids initiate apoptosis in the eosinophils and in some lymphocytes.

Stress and Disease

Stress plays an important role in individual and species survival, but it also participates in the development and aging of every individual. The quality, intensity, and duration of stress are important in determining the positive or negative effects on the organism.

There are two main conditions of the stress system that lead to pathology: an excessive and prolonged or a defective adaptive response to a stressor. In both cases, the dose–response relation between the potency of a stressor and the adaptive response of the organism is shifted to the left or right, respectively. Excessive or defective reactions to stressors that are associated with pathological or physiological states are summarized in [Table 1](#). More than half of the variance determining the stress response is due to inherited factors, whereas the remaining half is due to early-life constitutional factors and concurrent environmental input.

In the syndrome of major melancholic depression, a disproportionate activation of the generalized stress response is chronically manifested. Central activation with consequent elevation of CRH is followed by a blunted ACTH response of the pituitary to exogenous CRH, probably due to the downregulation of CRH receptors and/or increased glucocorticoid feedback. At autopsy, these patients have an increased number of CRH and AVP neurons in the paraventricular nucleus of the hypothalamus and hippocampal

Table 1 Pathological conditions associated with altered activity of the HPA axis

<i>Increased HPA activity</i>	<i>Decreased HPA activity</i>	<i>Disrupted HPA activity</i>
Severe chronic disease	Atypical depression	Cushing's syndrome
Melancholic depression	Seasonal depression	Glucocorticoid deficiency
Anorexia nervosa	Chronic fatigue syndrome	Glucocorticoid resistance
Obsessive-compulsive disorder	Hypothyroidism	
Panic disorder	Adrenal suppression	
Chronic excessive exercise	Obesity (hypoenergetic forms)	
Malnutrition	Nicotine withdrawal	
Diabetes mellitus	Vulnerability to inflammatory disease (Lewis rat)	
Hyperthyroidism	Rheumatoid arthritis	
Central obesity	Premenstrual tension syndrome	
Childhood sexual abuse	Postpartum mood and inflammatory disorders	
Pregnancy	Vulnerability to alcoholism	

atrophy. In addition, imaging and morphometric studies have shown that the pituitary and adrenals are enlarged. The sequelae of hypercortisolism include pseudo-Cushing's syndrome manifestation, osteoporosis, and opportunistic infections. Similar observations were made in patients with chronic active alcoholism, with anorexia nervosa, who were sexually abused in their youth, and with obsessive-compulsive disorders.

Another example of hyperactivation of the stress system is critical illness. When entering a chronic state, interleukin 6 and possibly other cytokines synergize with ACTH to maintain increased stimulation of the adrenal cortex. In this condition, a dissociation between ACTH and cortisol levels occurs. As in melancholic depression, these patients escape full HPA axis suppression following dexamethasone.

In the autoimmune-inflammatory syndrome of rheumatoid arthritis, a hypoactive HPA axis has been reported. It appears that a defective glucocorticoid response to inflammation is an important factor in the pathogenesis of this disease.

Disease and Stress

There are pathological conditions of the stress system leading to disease and, *vice versa*, diseases that alter the activity of the stress system in a pathological fashion.

Stress System Disorders

The adaptive response to stress has three components. First, stress has to be sensed. Sensory neural and hormonal pathways have developed to connect the outside world and the rest of the body to the central nervous system. Hypersensitivity or hyposensitivity to stressors may cause disproportionate responses, resulting in pathology. Therefore, disorders characterized by altered perception of signals to

the stress system cause inefficient responses to natural challenges, with the consequent development of secondary diseases.

The second component covers the calculation and integration of the information input, and the third component covers the response. Disorders of the central nervous system that influence these responses interfere with the stress system and develop pathology related to this interference.

The activation of the stress system is necessary to overcome homeostasis-threatening events, but excessive and prolonged activation may be self-destructive. Transient hypercortisolemia is necessary during surgery, sepsis, and other severe conditions, but hypercortisolemia also leads to hyperglycemia, hyperlipidemia-increased catabolism, and immune suppression – all states that, if chronically present, have major adverse effects on the body.

Diseases That Directly Influence the Stress System

Diseases generally disturb homeostasis and should be regarded as stressors. Conversely, every stressful influence that alters homeostasis of the organism in a long-term fashion could be regarded as a process that may cause disease.

Cushing's syndrome or Addison's disease leads to the disintegration of the stress system, which then fails to mount an adaptive response. In addition, severe sepsis leads directly to the activation of the stress system. Patients with these conditions develop multisystem disorders that result from excessive or defective cortisol effects on systems, whose proper function depends on optimal glucocorticoid activity.

Glossary

<i>Absorption</i>	The process of absorbing or being absorbed; great interest; entire occupation of the mind.
<i>Dissociation</i>	The act of dissociating or state of being dissociated; separation. In psychology, term used to describe the separation of whole segments of the personality (as in multiple personality) or of discrete mental processes (as in the schizophrenias) from the mainstream of consciousness or of behavior.
<i>Hypnosis</i>	The state of being hypnotized; abnormal sleep. There is no formal definition in the dictionary for hypnotizability or hypnotic capacity. This could properly be defined as a subject's ability to use a natural state of mind known as hypnosis.
<i>Suggestibility</i>	The ability to influence by suggestion.
<i>Trauma</i>	Bodily injury caused by violence; emotional shock (psychic trauma) with a lasting effect; a disordered psychic or behavioral state resulting from mental or emotional stress or physical injury.

Introduction

The word dissociation is defined as the act of dissociating or the state of being dissociated. It can also stand for the splitting off of a group of mental processes from the main body of consciousness. In psychiatry, the term is used to describe the reversible separation of elements of “identity, memory or consciousness” (APA, 2000) from the mainstream of consciousness or of behavior, as in dissociative amnesia, fugue, depersonalization, or dissociative identity disorder. The word comes from the Latin verb *dissociate*, meaning to separate, to disunite; *dis*, meaning asunder; and *sociare*, meaning to unite.

Thus, dissociation can be understood as the mechanisms by which we are able to separate mental processes and contents. Ordinarily, these are processed together. Normally, the (nonpathological) mechanism of dissociation allows us to carry on more than one complex task or action simultaneously by keeping out of consciousness routine experiences or tasks. For example, it allows a person to watch a television program while knitting or cooking. Similarly, it allows individuals to successfully drive their car while listening and learning from a book on tape.

Unconsciously, the mechanism of dissociation can also be elicited as an attempt to preserve some sense of control, safety, and identity in the face of overwhelming stress. Dissociation is usually elicited as a response to trauma that threatens personal physical integrity or the safety of a loved one, or as a response to extreme isolation and abandonment. Unfortunately, dissociative defenses give victims a false sense of control while immediately provides temporary relief from the full impact of the traumatic experience. Because the use of dissociation allows people to separate themselves from the awareness of danger, some trauma victims act as if the event is not happening. Yet others act as if it had never happened.

Pathological dissociation is usually the result of trauma. The form of trauma may vary widely, ranging from abandonment to overt physical trauma. Trauma may involve natural disasters (e.g., earthquakes, tornadoes, floods), man-made accidental disasters (e.g., war, nuclear plant explosions), large-scale man-made intentional disasters (e.g., the World Trade Center attack of 9/11 in New York City, the Oklahoma City bombing, school shootings, terrorism), or more personal traumas, such as rape, car accidents, or even a traumatic medical procedure. Probably among the most publicized of all forms of trauma are the victims of childhood physical and sexual abuse.

The traumatic experience invariably objectifies its victim. The sense of helplessness engendered by such situations creates sudden challenges to normal ways of processing perception, cognition, affect, and relationships. Trauma in the form of both natural disaster and human assault causes disruption to normal cognitive and affective processes and forces its victims to reorganize mental, psychological, and physiological processes in an attempt to prevent the immediate impact of the trauma. This reorganization may take the form of various forms of dissociative processes, fostering separation from painful surroundings and realities (derealization), or from the victim's own body (depersonalization). Even though such defenses may initially be adaptive, directed at maintaining control at times of overwhelming stress, some trauma victims develop persistent dissociative, amnesic, and anxiety-like symptoms. The ultimate sequelae of trauma for a substantial minority of its victims may be the development of traumatic stress disorders or dissociative disorders.

Dissociative disorders have been described in many cultures and settings, with women making up the majority of cases. Nearly 90% or more of cases reported in the literature are women. The most common dissociative disorder diagnosis is the not otherwise specified category, both in the United States and in non-Western countries, where dissociative trance and possession trance are the most common dissociative disorder diagnoses.

Dissociation as a pathological (i.e., psychiatric) phenomena was initially described by the French philosopher and psychologist Pierre Janet. Janet used the French term *désagrégation*, which carries with it a different and more accurate nuance than its English translation, dissociation. *Désagrégation* implies a separation of mental contents despite their general tendency to aggregate or be processed together. According to Janet, the problem experienced by patients suffering from dissociative phenomena is a difficulty in

integration of psychic processes, rather than a proliferation of components of consciousness, memory, identity, or perception. Janet (1989) viewed *désagrégation* as a purely pathological process, "a malady of the personal synthesis." Janet was also the first to study psychological trauma as a principal cause of dissociative phenomena. Unfortunately, during the twentieth century Janet's work and theories of dissociation as a pathological process were eclipsed by the emerging psychoanalytic theories proposed by Sigmund Freud. Freud's teachings and methods emphasized the mechanism of repression, rather than dissociation, as the driving force of his patients' problems. Nevertheless, early writings by Freud and his colleague Josef Breuer explored unconscious phenomena through an examination of seemingly similar dissociative phenomena. Infact, expanding on the theories on hysteria of their mentor, the French neurologist Jean Marie Charcot, Breuer and Freud suggested that the dissociative symptoms exhibited by their patients could be attributed to the patients' capacity to enter spontaneous and uncontrolled hypnoid states.

Based on observations of combat soldiers and former concentration camp inmates, Hilgard developed a neodissociation theory that revived interest in Janetian psychology and psychopathology. Hilgard's neodissociation model conceived of a mental structure with divisions that were horizontal rather than vertical, different from Freud's topographic model, which was composed of deeper and deeper layers of unconscious mental processing. Unlike Freud's system, Hilgard's model allowed for immediate access to consciousness of any of a variety of warded-off memories. In his model, amnesia was the crucial mediating mechanism that provided the barriers that divided one set of mental contents from another. Thus, he proposed the flexible and reversible use of amnesia as a key defensive tool.

Carl Jung had a unique insight in recognizing that the dissociability of the psyche is a fundamental process that extends along the continuum from normal mental functioning to abnormal states. Thus, Jung viewed the process of dissociation as a universal and necessary psychic activity for the development of personality through the differentiation of functions. On the other hand, he postulated that when the cohesion of consciousness was shattered by extreme traumatic experiences (e.g., childhood physical or sexual abuse), the natural process of differentiation of function was intensified, creating extreme dissociative splits between autonomous forces in the psyche, as observed in the cases of several psychiatric disorders, e.g., borderline personality disorder (BPD) or dissociative identity disorder (DID).

Models of Dissociation

Several models have been proposed to explain the process of dissociation. One such model, the neurological model, suggests that some underlying neurological process, such as hemispheric disconnection or epilepsy, causes the manifested clinical symptoms of dissociation. Several forms of epilepsy, particularly temporal lobe seizures, can manifest with rather complex behaviors (e.g., automatism), of which the subjects have little or no recollection. In other forms of epilepsy (e.g., petit mal seizures) subjects may experience depersonalization-like phenomena, reminiscence of dissociative phenomena.

The second proposed model is the role enactment model, also known as the social role demand theory. This model suggests that the symptoms associated with dissociative disorders represent an artificial social construct rather than a true psychiatric disorder. The proponents of this model suggest that dissociation is a clinical artifact created out of conscious or unconscious needs on the part of patients to capture the attention of their doctors. Some have even proposed a direct iatrogenic etiology in which therapists suggest the existence of symptoms (e.g., personality states). Finally, the autohypnotic model recognizes the connection between trauma, dissociation, and hypnotizability.

The third proposed model is the autohypnotic model. This theory recognizes and reconciles the connection between traumatic events, dissociative experiences, and hypnotizability. Thus, the autohypnotic model suggests that trauma victims dissociate or forget traumatic memories, using self-hypnotic mechanisms in order to keep them out of consciousness because reality is too painful to be faced. Memories may be stored at conscious and/or unconscious levels. The degree of amnesia varies, with some patients who have always remembered. Some remember only parts of the trauma. Yet in certain cases, some memories are transformed and others are interspersed with fantasy (e.g., cases of ritual abuse or alien abduction). Later on, some memories slowly leak into the conscious mind. Because full memories are not available it is difficult for patients to make sense of them. Some victims experience leaked memories in the form of flashbacks or dreams. Other trauma victims isolate themselves due to the shame they feel in relation to the suspected trauma.

Even though dissociated memories may be temporarily unavailable to consciousness, they may continue to influence conscious (or unconscious) experiences and behavior. Clinical experience suggests that dissociated information continues to affect patients' moods, behavior, and cognitive processes. It is common for

patients suffering from dissociative disorders to feel that something is wrong but to be unable to identify what. Many patients will experience a sense of discomfort, or sometimes even panic, when in specific situations. In fact, many of the symptoms experienced by trauma victims (e.g., flashbacks, psychosomatic symptoms) can be explained by the influence exerted by dissociated (forgotten or inaccessible) memories.

Nevertheless, it is important to remember that not everyone exposed to trauma will develop dissociative symptoms. In fact, studies conducted with war veterans reported that less than 25% of soldiers exposed to trauma during combat go on to develop severe dissociation or posttraumatic syndrome. This suggests that other factors may be involved in the production of dissociative and anxiety symptoms. A leading factor may involve the developmental stage during which the trauma occurs. Available data suggest that, as a rule, the earlier in life the trauma occurs, the greater the psychological sequelae caused. This is probably due, in part, to the defense mechanisms and coping styles that the victim has had an opportunity to develop prior to the occurrence of the trauma, which in turn will modulate the way in which the victim perceives the experience and adapts to its impact and consequences.

Putnam proposed the discrete behavioral states model of dissociative identity disorder. Forrest described a possible biological mechanism to support Putnam's theory by proposing the involvement of the orbital frontal cortex in the development of DID and suggesting a potential neurodevelopmental mechanism responsible for the development of multiple representations of the self. The proposed orbital frontal model integrates and elaborates on theory and research from four domains: the neurobiology of the orbital frontal cortex and its protective inhibitory role in the temporal organization of behavior; the development of emotion regulation, the development of the self, and experience-dependent reorganizing of neocortical processes. The hypothesis proposed by Forrest establishes that the experience-dependent maturation of the orbital frontal cortex in early abusive environments, characterized by discontinuity in dyadic socio-affective interactions between the infant and the caregiver, may be responsible for a pattern of lateral inhibition (i.e., dissociation or inhibition of conflicting subsets of self-representations that are normally integrated into a unified self). His basic idea is that discontinuity in the early caretaking environment is manifested in the discontinuity in the organization of the developing child's self.

Brenner has suggested that dissociation may be seen as a complex defense. Furthermore, he believes

that DID may be thought of as a lower level dissociative character, and that there is a unique psychic structure, which he calls the dissociative self, whose function is to create alter personalities out of disowned affects, memories, fantasies, and drives. As many other experts on dissociation have suggested, Brenner believes that this dissociative self must be dissolved during the therapeutic process in order for integration of alter personalities to occur.

In fact, recent scientific literature has focused on the characterological features of DID, thus extending the state versus trait debate to the realm of the dissociative disorders. This has led to the development of theories suggesting that DID may be a variant of, on a continuum with, or comorbid with the diagnoses of narcissistic and BPDs. Brenner suggested that DID would be best considered as a distinct characterological entity. He presented two theories, which described DID as a personality disorder whose predominant defense is dissociation. The more developed model, which possibly has more explanatory value, is the dissociative character. In this schema, DID would be considered a lower-level dissociative character, utilizing primitive forms of dissociation in which splitting is enhanced by an autohypnotic defensive altered state of consciousness. These patients experience altered states, which originate in response to the overstimulation stemming from external trauma, but which are reactivated in response to here-and-now intrapsychic conflicts.

Universality of Dissociation as a Syndrome

Dissociative symptoms have been reported in virtually every major psychiatric disorder and, in less severe forms, even in nonpatient (normal) populations. In the United States general (nonclinical) population, 6.3% of adults have reported three to four dissociative symptoms. Studies have suggested that dissociative disorders might comprise 5 to 10% of the psychiatric populations. Similarly, dissociative disorders have been described in many cultures and settings. Studies demonstrating prevalence rates have been conducted in Turkey, the Netherlands, Switzerland, Australia, Ethiopia, and Germany.

The Dissociative Disorders

The *Diagnostic and Statistical Manual*, 4th edition (DSM-IV) recognizes five different dissociative disorders. These include depersonalization disorder, in which patients feel detached from their own mental processes or body and which patients describe as a robot-like or out-of-body experience. Dissociative amnesia is a disorder in which patients exhibit an inability to recall important personal information.

The memory loss (amnesia) may apply to a part of the trauma (localized) or all (selective) of the traumatic experience. In extreme cases the amnesia may include personal information regarding the patient's entire life (generalized amnesia). Patients suffering from dissociative fugue suddenly go away, usually traveling far from home and developing a new identity while remaining amnesic to their past personal history. Patients suffering from DID exhibit two or more identities or personality states accompanied by frequent memory gaps (i.e., amnesia). Finally, there is a category called dissociative disorder not otherwise specified (NOS), by which patients exhibiting the core of dissociative symptoms but not fulfilling the diagnostic criteria of the previous four syndromes are classified. An example that may fit in this category is patients suffering from trance states.

Dissociative Amnesia (Psychogenic Amnesia)

The hallmark of this disorder is the inability to recall important personal information, usually of a traumatic or stressful nature, that is too extensive to be explained by ordinary forgetfulness. This is probably the most common of all dissociative disorders. In fact, amnesia is not only a psychiatric disorder by itself, but also a symptom, commonly found in a number of other dissociative and anxiety disorders. The highest incidence of dissociative amnesia has been described in the context of war and other natural and man-made disasters. Data suggest a direct relationship between the severity of the exposure to trauma and the incidence of amnesia.

Cases of dissociative amnesia usually share the following characteristics. First, the memory loss is episodic. That is, patients usually suffer the first-person recollection of certain personal events rather than knowledge of procedures (i.e., a person may not remember that he or she is a mechanic by trade or training, but is still able to intuitively and competently handle the tools). The memory loss involves a discrete period of time ranging from minutes to years. There seems to be a clear, dense amnesia, not a vagueness or inefficient retrieval of memories. There is usually no difficulty in learning new episodic information. The memory loss generally encompasses events of a traumatic or stressful nature.

In cases of dissociative amnesia patients are usually aware of their memory loss. Cases of dissociative amnesia can also be distinguished from amnesia of neurological origin by patients' intact cognition and capacity to learn new information. The primary problem in amnesia patients is a difficulty in retrieval rather than encoding or storage; thus, memory deficits are usually reversible. In fact, once the amnesia has cleared, normal memory function is resumed.

The epidemiology of this disorder is unknown. Nevertheless, dissociative amnesia is considered to be the most common of all dissociative disorders. The etiology of amnesic disorders is presumed to be posttraumatic, since they generally occur within the context of severe psychosocial stress. The duration of the disorder varies from a few days to a few years.

Even though it is possible to experience a single episode of amnesia, many patients have experienced several episodes during their lifetime. This is more common when the stresses that caused the initial episode are not resolved. The spontaneous resolution of the symptoms is rather common. In fact, many patients experience spontaneous recovery without more treatment than a protective environment. Sometimes more systematic treatment may be necessary.

The differential diagnosis of dissociative amnesia includes epilepsy, brain malignancy, head trauma, medication side effect (e.g., benzodiazepines use), chronic drug abuse and acute intoxication, cardiovascular and metabolic abnormalities, other dissociative disorders, an organic brain syndrome, a factitious disorder, and malingering.

Dissociative Fugue (Psychogenic Fugue)

Dissociative fugue is characterized by the sudden, unexpected travel away from home or one's customary place of daily activities, with inability to recall some or all of one's past. As in the previous disorder, amnesia is present, causing a sense of confusion about personal identity. On occasion, patients assume a new identity.

In contrast to dissociative amnesia cases, patients suffering from fugue states appear normal to the lay observer. Patients usually exhibit no signs of psychopathology or cognitive deficit. Fugue patients differ from those with dissociative amnesia in that the former are usually unaware of their amnesia. Only upon resumption of their former identities do they recall past memories, at which time they usually become amnesic for experiences during the fugue episode. Often, patients suffering from fugue states take on an entirely new (and often unrelated) identity and occupation. In contrast to patients suffering from DID, in fugue states the old and new identities do not alternate.

Not much is known regarding the etiology of this disorder. Nevertheless, the underlying motivating factor appears to be a desire to withdraw from emotionally painful experiences. Clinical data suggest that predisposing factors include extreme psychosocial stress such as war or natural and man-made disasters, personal and/or financial pressures or losses, heavy alcohol use, and intense and overwhelming stress

such as assault or rape. The onset of some fugue episodes may occur during sleep or be associated with sleep deprivation.

As in cases of acute dissociative amnesia, the onset of the disorder is usually associated with a traumatic or overwhelming event accompanied by strong emotions such as depression, grief, suicidal or aggressive impulses, or shame. Dissociative fugue is the least understood dissociative disorder. This may be due to the fact that most of these patients do not present for treatment. Usually they do not come to the attention of medical personnel until they have recovered their identity and memory and return home. Typically, patients seek psychiatric attention once the fugue is over and they are seeking to recover their original identity or retrieve their memory for events that occurred during the fugue.

Dissociative Identity Disorder (Multiple Personality Disorder)

DID is defined by the presence of two or more distinct identities or personality states that recurrently take control of behavior. This disorder represents the failure to integrate various aspects of identity, memory, and consciousness. Characteristics of this disorder are memory disturbances and amnesia. In contrast to other dissociative disorders, the degree of amnesia experienced in DID is usually asymmetrical. That is, it selectively involves different areas of autobiographical information, i.e., alters (personality states or identities) differ in the degree of amnesia for the experiences of other alters and the access to autobiographical information.

Usually there is a primary or host personality that carries the patient's given name. Often the host is not completely aware of the presence of alters. Because of the presence of amnesic barriers, different personalities may have varying levels of awareness of the existence of other personalities. On average there are 2 to 4 personalities present at the time of diagnosis, and usually up to 13 to 15 personalities are discovered during the course of treatment.

The symptoms that usually prompt patients or their families to seek treatment include memory deficits, moodiness, erratic and unpredictable behavior, depression, self-mutilation, suicidal ideation or attempts, and the overt manifestation of an alternate personality. Transition from one personality to another is usually sudden and is commonly triggered by environmental/interpersonal factors.

Alter identities may have different names, sexes, ages, and personal characteristics and often reflect various attempts to cope with difficult issues and problems. Alters can have a name and well-formed

personalities, e.g., Rose, an 8-year-old girl, or can be named after their function or description, e.g., the Angry One.

The factors that can lead to the development of DID are quite varied, but most authors seem to agree that physical and sexual abuse during childhood is the most commonly found etiological factor in these patients. In fact, a history of sexual and/or physical abuse has been reported in 70–97% of patients suffering from DID, with incest being the most common form of sexual trauma (68%). Other forms of childhood trauma that are associated with later development of DID include physical abuse other than sexual abuse (75%), neglect, confinement, severe intimidation with physical harm, witnessing physical or sexual abuse of a sibling, witnessing the violent death of a relative or close friend, traumatic physical illness on self, and near-death experiences.

The actual incidence and prevalence of this disorder are unclear. The estimated prevalence of DID in the general population has been reported to range from 0.01 to 1%. The average time from the appearance of symptoms to an accurate diagnosis is 6 years. The average age at diagnosis is 29 to 35 years. It has been described to be more common in women than in men by a ratio of 3–9:1. Female patients are also reported to present more personalities (average of 15) than men (average of 8).

There is a high incidence of comorbid psychiatric and medical syndromes. Of the psychiatric disorders, depression is the most common (85–88%), followed by posttraumatic stress disorder, BPDs, and substance abuse. There are a number of other psychiatric symptoms common to patients with DID, including insomnia, suicide attempts or gestures, self-destructive behaviors, phobias, anxiety, panic attacks, auditory and visual hallucinations, somatization, conversion reactions, and psychotic-like behavior.

As in cases of dissociative amnesia and fugue, the differential diagnosis of dissociative disorders includes an organic condition (e.g., temporal lobe epilepsy, brain malignancy, head trauma, medication side effect, drug abuse, and intoxication), other dissociative disorders, psychotic disorders (e.g., schizophrenia), factitious disorder, and malingering.

Depersonalization Disorder

Depersonalization is characterized by persistent or recurrent episodes of feelings of detachment or estrangement from one's self. Depersonalization disorder is primarily a disturbance in the integration of perceptual experience. Individuals commonly report feeling like a robot or as if they are living a dream or a movie. Patients suffering this condition describe

their experience as if they were an outside observer of their own mental processes and actions. In contrast to delusional disorders and other psychotic processes, reality testing is intact. The phenomena associated with depersonalization are not uncommon. In fact, depersonalization is seen in a number of psychiatric and neurological disorders, including agoraphobia and panic disorder, acute and posttraumatic stress disorder, schizophrenia, other dissociative disorders, personality disorders, acute drug intoxication or withdrawal, psychotic mood disorders, epilepsy, Ménière's disease, sensory and sleep deprivation, hyperventilation, and migraine headaches. In fact, people with no psychiatric condition can transiently experience symptoms of depersonalization. Because of this it is important that the diagnosis is applied only when the presence of symptoms causes severe impairment in functioning or marked distress.

The incidence and prevalence of this condition are unknown. The symptom of depersonalization has been described as being the third most common psychiatric symptom, after depression and anxiety. It is believed that under severe stress, up to 50% of all adults have experienced at least one brief episode of depersonalization. On the other hand, up to 12–46% of normal college students, nearly 30% of individuals exposed to life-threatening danger, up to 40% of hospitalized psychiatric patients, and about 69% of patients with panic disorder have experienced transient episodes of depersonalization. Episodes of depersonalization may also occur as a symptom of alcohol and drug abuse, as a side effect of prescription medication, and during stress and sensory deprivation. The sex distribution is unknown.

Theories for the etiology of this disorder range from the completely physiological, such as anatomical defects similar to epilepsy, to the purely psychological, such as a defense against painful and conflictual affects or the split between observing and participating ego/self, to combinations of all of the above as the result of a preformed functional response of the brain as an adaptation to overwhelming trauma. In any event, exposure to traumatic experiences seems to be the common etiological factor in this disorder. The course of the illness is usually chronic, with episodes of exacerbation usually following exposure to real or perceived stress.

Treatment

To date there are no controlled studies addressing the treatment of any of the dissociative disorders. All the information available reflects the experience and case reports of clinicians and specialized treatment centers. No single treatment modality has been

systematically studied in this patient population. Similarly, there are no established pharmacological treatments except for the use of benzodiazepines or barbiturates for drug-assisted interviews.

Dissociative Amnesia (Psychogenic Amnesia)

Before treatment is started it is necessary to establish that the amnesia or fugue state is of dissociative (psychogenic) origin, ruling out the possibility of a neurological disorder such as temporal lobe epilepsy. Usually the initial step in the treatment is to provide a safe environment. Simply removing the person from the threatening situation and providing security and protection has allowed for the spontaneous recovery of acute episodes. At times additional help may be needed to obtain the necessary biographical information or to facilitate the patient's recall. Among the adjuvants commonly used, hypnosis and barbiturate- or benzodiazepine-facilitated recall are the most popular and better described.

No studies have addressed the efficacy of hypnosis in the treatment of dissociative amnesia. Nevertheless, most researchers in this area agree that hypnosis is a very useful tool for the recovery of repressed and dissociated memories. Once the amnesia has been reversed, treatment should be directed at restructuring the events and defining the factors that led to the development of the amnesia. This is followed by the establishment of appropriate defenses and mechanisms to prevent further need for dissociation. This is best done within the context of more extensive therapeutic work.

Dissociative Fugue (Psychogenic Fugue)

The treatment should involve provision of rest and assurances of safety, development of a trusting therapeutic relationship, recovery of personal identity, review of triggers or factors associated to the onset of the fugue, reprocessing of traumatic material, reintegration of traumatic memories into personal history, and returning the patient to his or her previous life.

Hypnosis and drug-facilitated interviews have commonly been used during the stages of recovery of personal identity and memories associated with the onset of the fugue. Except for the facilitation of memory retrieval (narcosynthesis) or diminution of anxiety related to the therapeutic process, no pharmacotherapeutic agents have been systematically studied in the treatment of this condition. The treatments for acute dissociative amnesia and fugue states have been generally similar. Traditionally, hypnosis and amytal narcosynthesis were the tools of choice

for the recovery of dissociated material in subjects suffering from both amnesia and fugue states. In fugue cases, treatment should be undertaken as quickly as possible, while the repressed material is more readily accessible and before the memories have an opportunity to consolidate into a nucleus, as this may increase the possibility of future flight episodes. Patients may also experience spontaneous memory recovery upon removal from the stressful situation, when exposed to cues from their past, or when they feel psychologically safe. Psychodynamic psychotherapy may help to address the conflicts that precipitated the amnesia or fugue, thereby reducing subsequent dissociation under stress.

Dissociative Identity Disorder (Multiple Personality Disorder)

To date, there are no studies demonstrating the efficacy of pharmacological agents in the treatment of DID. As in the other dissociative disorders, pharmacological agents do not seem to address the disorder, but may serve as adjunct treatment of accessory symptoms (e.g., comorbid insomnia, anxiety and depressive symptoms).

Almost every psychotherapeutic and psychopharmacological treatment modality has been applied to patients suffering from DID, from group psychotherapy to family therapy, from antidepressants to antipsychotics to anticonvulsants to β -blockers, from hypnosis to eye movement desensitization and reprocessing (EMDR) to electroconvulsive therapy (ECT). All of them have been shown to have various degree of success.

In general terms, the treatment of DID involves (1) development of a therapeutic relationship based on safety and trust, (2) negotiation with the patient about cooperation with treatment, (3) development of a contract against harm to self or others, (4) history taking and understanding personality structure, (5) abreaction and working through of traumatic experiences and frequently repressed or dissociated material, (6) negotiating and modulating conflicts among aspects of identity and personality states, (7) development of mature and more appropriate, nondissociative defenses, and (8) working toward integration of alters.

Techniques such as hypnosis can facilitate control over dissociative episodes and integration of traumatic memories (see next section for details). Efforts at development of a social network and support system are helpful. Once integration has been achieved, further work is needed to deal with residual or renewed dissociative responses to external stress or internal conflicts and to further integration with society.

The treatment of DID is usually arduous, painful, and prolonged. Even though the ultimate goal is the achievement of integration, in some cases a reasonable degree of conflict-free collaboration among the personalities is all that can be achieved. Among clinicians, the most common treatment modality used is individual psychotherapy facilitated by the use of hypnosis. The average DID patient is seen twice a week for a period of about 4 years before integration is achieved. Clinical experience seems to suggest that patients suffering from DID do not experience spontaneous remission of their illness if left untreated.

Depersonalization Disorder

Episodes of depersonalization are usually transient and thus remit without formal treatment. Recurrent or persistent depersonalization may require intervention. Treatment modalities include paradoxical intention, record keeping and positive reward, flooding, psychodynamic psychotherapy, psychoeducation, psychostimulants, antidepressants, antipsychotics, anticonvulsants, benzodiazepines, ECT, and hypnosis. In considering somatic treatments for depersonalization, it is important to determine whether the complaint represents the primary condition or whether it is secondary to another disorder. When an additional psychiatric diagnosis (e.g., anxiety or depression) is present and successfully treated, the symptoms of depersonalization usually improved or resolve. Thus, the most important aspect of the treatment of depersonalization disorder is careful assessment of possible psychiatric comorbidity and treatment of those conditions.

As a symptom, depersonalization responds to self-hypnosis training. Often, hypnotic induction will induce transient depersonalization symptoms in patients. This is a useful exercise because having a structure for inducing the symptoms provides patients with a context for understanding and controlling them. Individuals for whom this approach is effective can be taught to induce a pleasant sense of floating lightness or heaviness in place of the anxiety-related somatic detachment. Often, the use of an imaginary screen to picture problems in a way that detaches them from the typical somatic response is also helpful.

Hypnosis as a Treatment Tool in the Psychotherapy of Dissociative Disorders

Traumatic memories may be elicited or spontaneously emerge during the course of psychotherapy without the utilization of any technique for memory enhancement. Nevertheless, there may be instances when the judicious use of hypnosis as adjuvant to

psychotherapy is recommended. For instance, hypnosis may facilitate access to repressed memories that have not emerged using other methods. Clinical experience suggests that many trauma victims respond to the traumatic event by using dissociative-like defenses during or after the trauma. In cases of repeated trauma, some victims learn how to trigger these dissociative responses (self-hypnosis-like defenses) in order to avoid further suffering. The structured use of a therapeutic hypnotic induction may elicit dissociative phenomena, as seen during the administration of the hypnotic induction profile. If needed, hypnosis can be helpful in facilitating controlled access to dissociated personalities and can be used to simply call up different identities or personality states as needed during the therapeutic process. More importantly, teaching patients to use self-hypnotic techniques to access alter states helps patients understand that they can have control over traumatic memories and experiences, leading to a way to control the episodes of spontaneous dissociation (e.g., flashbacks, personality states).

Studies show that patients suffering from dissociative disorders are highly hypnotizable. Thus, if hypnotic-like states are elicited during traumatic experiences and some patients unknowingly used them in order to dissociate from their surroundings, it makes sense that the very entry into this same state could lead to the retrieval of memories and effects associated with the original trauma, as would be predicted by the theory of state-dependent memory. Hypnosis then can be useful both as a diagnostic tool and as a powerful therapeutic technique. Properly done, hypnotic techniques can effectively facilitate symbolic restructuring of the traumatic experience.

The condensed hypnotic approach using hypnosis as a facilitator has two major treatment goals: to make conscious previously repressed traumatic memories and to develop a sense of congruence between memories associated with the traumatic experience and patients' current realities and self-images. These goals can be achieved by the use of six consecutive and interdependent steps or stages. Each of them is designed to help patients work through previously repressed memories, while enhancing control over their dissociative mental processes. The six stages are confrontation, condensation, confession, consolation, concentration, and control.

During the first stage, confrontation of the trauma, patients come to terms with the factors and events associated to the trauma. The therapist's role at this time is that of a supportive, nonjudgmental listener, who avoids suggesting or implanting facts.

During the second stage, hypnosis is used to facilitate a condensation of the traumatic memories. There is little need to force patients to recount all the details

of every traumatic episode. Thus, therapists can use hypnosis to define segments or episodes that summarize the traumatic experience without allowing patients to compulsively relive the entire trauma.

This is followed by the stage of confession of feelings and experiences that patients are profoundly ashamed of and may have never told anyone before. During this stage the therapist should convey a sense of being present for the patient, while remaining neutral.

The recovery and confession of traumatic memories is often accompanied by an immense sense of shame and sorrow. Thus, during the next stage, consolation, the therapist is more active and emotionally available to patients. It is appropriate to make empathic comments about the impact the experience must have had on them. Because of the frequent incidence of boundary violations during the episodes of abuse, therapists are warned to be extra careful regarding the ways in which care and empathy are expressed. Therapists are reminded of the possibility of the development of traumatic transference relationship at this point. That is, patients may interpret the therapist's interest in their past as a pretext for making them suffer again. Because of the mobilization of painful emotions, therapists are experiencing as hurting rather than helping them.

The intense concentration characteristic of hypnosis facilitates therapeutic work on selective traumatic memories. The structure of the hypnotic trance allows patients to turn on memories in the secure environment of the therapy session, while allowing them to shut them off once the intended work has been completed at the end of the session. Hypnosis also provides the flexibility to work on one aspect of the memory without requiring patients to recall the entire trauma. Therefore, the hypnotic process promotes concentration on the desired goal while helping patients remain in control. Using the structured experience of the therapeutic trance, patients learn how to think about the trauma in a constructive fashion.

Finally, patients should be helped to achieve an enhanced level of control, while restoring a sense of mastery and order in their lives. In order to achieve that goal, therapists guide the therapeutic interaction in such a way that patients' sense of control over their memories is enhanced. Patients are allowed to remember as much as can safely be remembered now, rather than pushed to remember the entire event at the therapist's will or in a compulsive fashion. The therapeutic use of self-hypnosis teaches patients that they are in charge of the experience, thus they can regain control of their memories. It allows patients to learn to trust their own feelings, perceptions, and

judgments. An important aspect in enhancing patients' sense of mastery is for them to learn not only how to control memories and symptoms, but also, equally important, when to ask for help.

Legal Ramifications of Memory Work

Every treatment involving potential repressed memories or childhood abuse must be preceded by a thorough explanation of the therapeutic and legal ramifications and a complete informed consent. Because of these potential problems some courts have restricted the admissibility of the testimony of hypnotized witnesses. Patients need to be warned about the fallibility surrounding hypnotically (or indeed any, even nonhypnotically) recovered memories, including the possibilities of confabulation, concreting, and the difficulty of differentiating between fantasized or remembered memories. It is difficult to avoid potential contamination using any memory enhancement (e.g., imagery work, hypnosis, EMDR, and conventional psychotherapy); thus, the therapist must use a neutral tone throughout the entire treatment. If hypnosis is to be used, therapists may guide patients through the experience, but at all times must avoid using leading or suggestive questions. The goal is to avoid contamination by introducing or suggesting information during the course of treatment. Indeed, hypnosis and any other nonhypnotic method of memory enhancement, including police interrogation, can distort memory by any of three ways: confabulation (the creation of pseudomemories, which are then reported as real); concreting (an unwarranted increased sense of confidence with which hypnotized individuals report their memories, whether these are true or false), or as the result of an additional recall trial.

More recently, there has been concern about the creation of false memories. Nevertheless, we must remember that the mind is not an accurate tape recorder that registers every experience we have. Because of the way people register, encode, and recover filed memories, false memories are by no means rare. In fact, most people probably are in doubt about certain aspects of their past. At times it may be difficult to differentiate things that we have seen, said, or done from those we have dreamed or just imagined. It is very likely that the most frequent source of false memory is the accounts we give to others of our experiences. Usually, such accounts are almost always made both more simple and more interesting than the truth. In fact, memory can be understood as a capacity for the organization and reconstruction of past experiences and impressions in the service of present needs, fears, and interests. Thus, therapists must be aware that not every memory recovered

with the use of hypnosis (or any other method of memory enhancement) is necessarily true. Hypnosis can facilitate improved recall of both true as well as confabulated material.

If memories of abuse are recovered, we do not encourage our patients to take legal action. There is no scientific evidence indicating that confrontation with alleged perpetrators of childhood abuse provides any therapeutic benefit to patients. The same is true for the pursuit of legal action or retribution toward perpetrators. It is impossible for therapists or the courts to be certain of the veracity of the memories recovered by either conventional therapy or hypnosis. Without objective external confirmation, therapists cannot distinguish among memories that are real, those that are the result of confabulation, and those that result from a combination of both. Furthermore, clinical experience in abuse cases suggests that not only would it be difficult to substantiate many of the allegations, but also little can be done in order to protect patients from the embarrassment, humiliation, and further trauma that would be imposed on them by virtue of the legal proceedings.

Several professional organizations have established clear guidelines regarding the use of hypnosis in instances where hypnosis is used as a method of memory enhancement. The guidelines suggest that when hypnosis or any other memory enhancement method is being used for forensic purposes or in the context of working out traumatic memories, especially those related to childhood physical and/or sexual abuse, multiple steps should be applied to minimize the possibility of memory contamination and maximizing the integrity of original memory.

Introduction

Assessment of Distress

Influences on Distress

Personality and Distress

Psychological Concomitants of Distress

Glossary

<i>Affect</i>	Emotional or feeling states, including specific emotions such as anxiety and depression.
<i>Neuroticism</i>	A personality trait associated with a predisposition to experience negative affect.
<i>Self-regulation</i>	The motivational and cognitive processes controlling goal-directed personal adaptation to the external environment.
<i>Stress</i>	The processes and responses associated with adaptation to demanding or challenging environments.
<i>Trait</i>	A personal disposition or characteristic showing long-term stability and influencing behavior in a range of situations

Introduction

Distress is an imprecise term that typically refers to unpleasant subjective stress responses such as anxiety and depression. It is also sometimes used to describe behaviors and medical symptoms (e.g., somatic distress). The concept of distress derives from Selye's general adaptation syndrome (GAS), the generalized temporal sequence of physiological and psychological stress responses that may be elicited by noxious or threatening life events. Often, stress responses are characterized by difficulties in adapting to the external stressor (distress), although stress may sometimes have a stimulating, energizing effect (eustress). Distress may thus be conceptualized as the internal strain provoked by an external stressor. However, this simple metaphor has been largely superseded by the view of Lazarus that stress responses reflect dynamic person–environment relationships. From this perspective, distress signals

that adaptation to environmental demands is taxing or unsuccessful.

This article reviews the assessment of distress, the roles of situational factors and personality in generating distress, and its psychological significance, including clinical implications. Contemporary research on distress is dominated by two themes. The first is the extent to which a global distress concept is to be preferred to more specific negative affective responses such as anxiety, depression, and anger. The second theme is that distress must be understood within a wider framework of the person's active attempts to adapt to the physical and social environment.

Assessment of Distress

Distress is a broad label for a variety of stress responses, and so there is no single, generally accepted means of assessment. Typically, the measurement of distress is questionnaire-based, although, especially in animal and child research, distress may be operationalized as behaviors such as vocalizations. Approaches to assessment vary in two respects: (1) the time scale over which distress is measured, and (2) the breadth of distress symptoms encompassed. Distress is typically assessed over the following time scales:

1. A transient state lasting for a few minutes, that is, the person's immediate state of mind.
2. An episodic condition lasting for weeks or months, such as the distress provoked by a life event or a short-lived clinical disorder.
3. A personality trait that may show stability over decades, such as trait anxiety.

The narrowest operationalizations of distress focus on negative affects such as anxiety and depression. Spielberger pioneered questionnaires that assess these constructs at the state and trait levels. Depending on the context, other indices of distress may be used in tandem with scales for negative affect. Distress may also describe cognitive responses, such as worry, lowered self-esteem, and lack of perceived control. In life event research, indices of distress may include difficulties in social functioning and health problems. Specialized measures are used in specific contexts, such as scales for marital distress, trauma symptoms, and health concerns. Somatic distress measures have been developed on the basis that self-reported medical symptoms tend to intercorrelate. Hence, different measures of distress probably relate to different underlying constructs.

Distress may be defined more precisely through multivariate psychometric research. Studies of mood have identified orthogonal dimensions of negative affect and positive affect, such that negative affect is a superordinate category relating to tension, unhappiness, irritability, and other negative affects, whereas positive affect covers states such as happiness and energy. The tripartite model of Mineka, Clark, and Watson proposes that a general factor of distress is common to mood and anxiety disorders. Specific disorders are differentiated by two further factors of anhedonia (characteristic of depression) and hyperarousal (elevated in panic disorders). The model has generally been well supported in studies of patient groups and by confirmatory factor analyses, although some studies have failed to confirm its predictions regarding the characteristics of specific disorders.

Other research has explored the expression of distress as a transient state. Most simply, distress may be identified with negative affect; many studies of mood discriminate negative and positive affect as fundamental dimensions. However, the state model of Matthews defines distress more precisely as an affective-cognitive factor, defined by tension, unpleasant mood, and cognitions of lack of control and low confidence. Distress is distinct from the two further broad state factors of task engagement (e.g., energy and task motivation) and worry (e.g., self-focused attention and intrusive thoughts).

Influences on Distress

Distress reflects both situational influences, such as life events, and intrapersonal influences, such as personality traits. This section reviews situational influences, investigated either through controlled experiments or correlational studies of real-life stressors. Events that threaten or damage the person's well-being often provoke distress. Environmental factors promoting distress include (1) traumatic events, (2) physical factors such as loud noise, (3) social factors such as criticism by others, and (4) ill health. The adverse effects of agents of these kinds are well documented, although there is considerable variation in their effects across individuals and across different occasions. However, there are competing physiological, cognitive, and social accounts of the mechanisms that link these external stressors to psychological stress responses.

Physiological Influences

Historically, the distress concept has been important to physiological research, for example, as a concomitant of Selye's GAS. Physiological studies of distress focus primarily on the brain mechanisms that may

output and regulate negative affect. Evidence for a biological basis for distress is provided most directly by studies of brain damage in humans and animals. For example, damage to the amygdala may provoke extreme emotional responsivity. Learning studies link the central nucleus of this structure to fear conditioning, such that it may function as the brain's emotional computer. In humans, damage to the frontal lobes seems to provoke disinhibition syndromes in which the disruption of emotional response is accompanied by the loss of behavioral control. Pharmacological studies allow negative affects to be linked to the neurotransmitters sensitive to the drug concerned. Different negative emotions may be controlled by different brain systems: anxiolytic drugs operate through benzodiazepine receptors, and anti-depressants such as fluoxetine (Prozac) operate through serotonergic pathways. Indeed, brain-imaging studies show that distress correlates with the activation of multiple cortical and subcortical areas. The key issue is the functional organization of these different sites, but it remains controversial whether distress can be linked to a single brain system associated with response to punishment. Some animal models of basic emotions replace the concept of general distress with an account of multiple brain systems for specific emotions including anger, fear/anxiety, and disgust.

Davidson links general distress to a withdrawal system supported by multiple brain structures including the right prefrontal cortex and amygdala. However, anxiety and depression are differentiated by other frontal systems, so that anxiety relates to increased right anterior activity and depression relates to increased right frontal activity. These hypotheses have been tested, with mixed success, in studies using the electroencephalogram (EEG). Another line of evidence is provided by psychophysiological studies that link anxiety states to the fight-or-flight reaction and to arousal of the sympathetic branch of the autonomic nervous system.

Contemporary studies aim just to establish correspondences between subjective affect and brain processes, but they also aim to establish that affective responses are embedded within a functional system that controls the organism's adaptation to a particular type of stimulus or event. Gray and his colleagues developed a detailed animal model that distinguishes three such systems. In the most recent version of this reinforcement sensitivity theory (RST), the systems are as follows. A fight-flight-freeze system (FFFS) is activated by signals of punishment and nonreward and may elicit various avoidance behaviors. A behavioral activation system (BAS) is activated by reward and nonpunishment, producing approach behaviors.

A behavioral inhibition system (BIS) is activated by conflict between FFFS and BAS, generating anxiety and heightened attention to threat. Hence, subjective distress is a concomitant of the adaptive processes linked to both the FFFS and BIS, which tend to operate jointly in managing response to punishment. There is extensive evidence on the effects of anxiolytic drugs in animals that supports the model, but its application to human emotional distress and anxiety remains contentious.

Cognitive Influences

Cognitive models of stress are supported by experimental studies demonstrating that both the psychological and physiological impact of stressors are moderated by the person's beliefs and expectancies. For example, negative moods may be induced by suggestive techniques such as reflecting on negative events or making statements that one is unhappy. Distress in the workplace reflects not just work demand but also perceived control and decision latitude. Appraisal theories of emotion seek to link affect to the person's evaluation of external stimuli and their personal significance. Anxiety may then relate to appraisals of personal threat and uncertainty, and depression may relate to uncontrollable personal harm. Appraisal is not necessarily accessible to consciousness, and there may be several distinct appraisal processes operating in tandem. Appraisal theories tend to focus on the differing cognitive antecedents of specific emotions rather than on undifferentiated distress. Studies of transient distress measured as a unitary state show that it relates to appraisals of threat, loss, and uncontrollability of events and to use of emotion-focused coping strategies such as self-criticism.

The transactional stress theory of Lazarus embeds appraisal within a wider matrix of person-environment interaction within which negative emotions are tied to core themes describing the person-environment relationship. Core relational themes also relate to action tendencies. Transactional theory emphasizes the person's active attempts to cope with threatening or damaging events. In general, distress is likely to develop when the people appraise themselves as failing to cope adequately and as lacking in personal control over significant events. Contemporary theory also emphasizes the differing relational themes associated with different negative emotions. The dynamic nature of the stress process is supported by evidence from longitudinal studies for reciprocal relationships between distress and life events and between distress and health perceptions. In cases of chronic distress, negative cognitions drive distress responses that in turn feedback into further

negative cognitions. This harmful feedback loop may be accentuated by metacognitions that maintain the focus of attention onto stress symptoms and reinforce negative self-referent beliefs.

Social Influences

The disruption of social relationships associated with bereavement, marital discord, and unemployment are among the most potent factors eliciting distress. Conversely, the availability of social support often functions to alleviate stress responses. Social psychologists characterize as inadequate attempts to locate distress solely within the individual. Instead, distress may reflect people's discourses about their problems and their interpersonal interactions within a social and cultural context. For example, Oatley has attributed depression to loss of socially defined roles. Social psychologists also emphasize the importance of the expression and display of emotion that reflects social motivations and norms.

Personality and Distress

Neuroticism and Negative Affect

Some individuals appear to be generally more distress-prone than others. Psychometric and experimental studies identify stable personality traits that relate to the person's predisposition to experience negative emotion. Eysenck identified a dimension of neuroticism associated with a low threshold for emotional arousal. A similar dimension corresponds to one of the factors described by the five factor model of personality. Studies of temperament in infants and children, based on observations of behavior, also identify negative affectivity or distress-proneness as a fundamental dimension.

Neuroticism predicts negative moods such as depression and anxiety, although the strength of the relationship varies with situational stressors. It also predicts vulnerability to worry and disturbances of cognition. The association between neuroticism and distress is substantiated by both controlled experimental studies and field studies of everyday mood using diary or experience-sampling methods. Neuroticism is also elevated in patients suffering from emotional disorders. Longitudinal studies suggest that neuroticism is a factor predisposing clinical disorder, although there is some reciprocity between the personality trait and disorder. Elevated neuroticism may also be an outcome or a scar of mental illness. In addition, both the Eysenck and five factor models include an extraversion-introversion factor. Extraversion relates primarily to happiness and positive affect but also correlates negatively with distress

measures to some extent. One influential view is that neuroticism is essentially a dimension of negative affectivity, whereas extraversion may be identified with positive affect, although this perspective may be oversimplified.

Neuroticism also relates to self-reported somatic distress and medical symptoms, including various psychosomatic conditions. It remains controversial whether more neurotic individuals are genuinely more prone to illness or whether they are just prone to complain about physical symptoms. However, a causal role for neuroticism is suggested by growing evidence that various negative affects, including depression, anger, and anxiety, operate as risk factors for illnesses, including coronary heart disease, although the effect sizes for the association between distress and illness are often small.

Current personality models generally adopt an interactionist or diathesis–stressor perspective, such that the distress response depends on the interaction of personal and situational factors. Hence, although more neurotic individuals are more vulnerable to distress, the extent to which they experience greater distress than less neurotic people on a given occasion varies with situational factors. A more subtle view of neuroticism is also suggested by life event research. Consistent with the negative affectivity hypothesis, more neurotic individuals seem to experience life events as more distressing. However, neurotic people also seem to experience a higher frequency of life events, which may reflect behavioral difficulties in adapting to life circumstances. For example, neuroticism relates to a higher frequency of interpersonal conflicts. Thus, there are at least three causal paths that may link neuroticism to distress: (1) high neurotics may be generally distress-prone, independent of external circumstances; (2) high neurotics may react to external events with elevated distress; and (3) high neurotics may behave in ways that elicit a higher frequency of distressing events. The dynamic nature of distress response is demonstrated also in studies of temperament in children. Overly distress-prone infants may be perceived as whiny or clingy, eliciting parental annoyance or neglect, which provokes further dysregulative responses from the child.

Other Traits

Various more narrowly defined traits are associated with vulnerability to distress. Spielberger's anxiety and depression measures are among the best known. According to Spielberger, trait anxiety represents a predisposition to experience transient state anxiety in threatening environments, but, consistent with interactionism, the trait-anxious individual does not experience state anxiety on all occasions.

Experimental studies suggest that trait anxiety correlates with state anxiety under conditions of ego threat, such as personal criticism. Negative affect is central to the definition of the Spielberger traits. Other traits such as optimism/pessimism, self-focus of attention, self-efficacy, and attributional style are cognitively defined, but correlate nevertheless with distress indices.

Distress-related traits tend to intercorrelate with one another and also with broader measures of neuroticism and negative affectivity. One view is that the various traits predict distress because they overlap with neuroticism and that the narrower trait constructs may add little to the broad trait. It is plausible that neglect of neuroticism as a confound of other traits has added unduly to the complexity of the field. Nevertheless, there is evidence for discriminative validity for traits such as optimism/pessimism and self-focus of attention; distress is best predicted from multiple traits.

Contextualized Traits

Neuroticism and other traits appear to act as generalized factors predisposing distress across a variety of contexts. However, in many cases people possess traits linked to specific contexts that predict distress over and above more generalized traits. A paradigmatic case is test anxiety. Sarason has developed scales that ask respondents specifically about their thoughts and feelings when required to take tests and examinations. People show stable individual differences in vulnerability to test anxiety that predict how they feel and perform in examination settings. Researchers have focused on evaluative anxiety in various other settings, using measures of social anxiety, math anxiety, computer anxiety, and so forth. Such measures typically correlate with neuroticism, but have better predictive validity in the appropriate context. The contextualized trait may reflect both neuroticism and the person's more specific stable cognitions of the context concerned. Much of this work has focused on anxiety as a distress symptom, but it is likely that contextualized traits predict other distress symptoms in a similar way. For example, individuals vulnerable to driver stress are prone to experience both anxiety and unhappiness during vehicle operation.

Psychological Explanations for Distress Vulnerability

There are competing explanations for individual differences in vulnerability to distress. Biological and cognitive models have been most fully articulated. Social psychological explanations are also relevant, although progress has been retarded by the reluctance

of social psychologists to accept the validity of traits. Biological explanations are bolstered by demonstrations from kinship and adoption studies that distress-related traits are partially inherited. The tendency for distress vulnerability to run in families relates more to genetic predisposition than to the influence of the common family environment. There is also an extensive literature on psychophysiological and biochemical correlates of neuroticism and other traits, although results are often weak or inconsistent. Hence, the pathways connecting genes for distress-prone personality to specific brain mechanisms are poorly understood, although various theories have been advanced. Eysenck claimed that neuroticism related to the sensitivity of the limbic system to emotional arousal; Gray's RST links trait anxiety more specifically to the BIS and (possibly) FFFS systems previously described.

Cognitive explanations are supported by evidence that traits relate to the constructs of the transactional model of stress, especially appraisal and coping. Many studies have shown that neuroticism, trait anxiety, and trait depression relate to a distinctive style of cognition of environmental demands. Individuals with these characteristics are prone to a variety of negative self-appraisals; they appraise the world as demanding and threatening and appraise themselves as ineffective in dealing with external demands. More neurotic individuals are prone to coping with potentially stressful events through emotion-focused strategies such as ruminating on their problems or criticizing themselves. Such strategies are frequently maladaptive and may sometimes even exacerbate the problem and contribute to clinical disorder. To a lesser degree, neuroticism also relates to avoidance of the problem and to reduced task-focused coping.

Psychological Concomitants of Distress

Distress has various behavioral correlates including the impairment of objective performance, bias in selective attention, and overt clinical symptoms. These findings are explained by theories of self-regulation pioneered by Carver and Scheier and elaborated as a general theory of distress by Wells and Matthews. In these models, self-regulation operates homeostatically to reduce the discrepancies between actual and preferred status. Distress signals self-discrepancy and the need for coping efforts to reduce self-discrepancy and maintain adaptation to the external environment. The regulatory system may have physiological as well as psychological expressions. It also operates within a social context in that interactions with others provide strong cues toward actual status and in that societal and cultural norms are reflected in part by

ideal status. Experimental studies of attention and performance identify biases in the cognitions supporting self-regulation, which may be the source of clinical disorders associated with distress.

Performance Impairment

Trait and state distress measures are associated with slower and/or less accurate performance on a variety of tasks. Both anxiety and depression tend to be associated with performance impairment. Contextualized distress measures are also typically associated with performance impairments within the context concerned; for example, test anxiety predicts poorer examination performance. Anxiety studies show that it is the cognitive rather than the emotional aspects of the anxiety state that interfere with performance. Self-referent worries appear to be especially damaging because attention or working memory may be diverted from the task at hand to personal preoccupations. The detrimental effects of depression have been similarly ascribed to worry and rumination. Loss of performance may reflect loss of attentional resources, controlled processing, or working memory.

The impact of distress on performance depends on motivational factors. Performance may be maintained or even enhanced when good performance is appraised as instrumental in relieving distress through compensatory effort. Conversely, decrements are more likely when motivation and effort are low. The maintenance of performance effectiveness through effort is more likely in anxiety than in depressed states. It appears that impairment is not a fixed cost of distress but a consequence of a style of self-regulation that promotes worry, self-focus of attention, and emotion-focused coping at the expense of performance goals.

Cognitive Bias

Distress is often associated with enhanced processing of negative stimuli. Such effects have been demonstrated in studies of experimentally induced moods, in studies comparing the performance of distressed patients with controls, and in studies comparing non-clinical groups selected for high and low distress. Some of the most reliable effects are found in studies of anxiety and selective attention. Anxious individuals are slow to name the color in which threat-related words are printed (the emotional Stroop effect), and they also appear to attend preferentially to threat stimuli in other paradigms. Other distressed groups are similarly biased toward negative stimuli congruent with their source of distress. These effects may reflect either an automatic bias toward threat stimuli in vulnerable individuals, deliberately chosen strategies, or both voluntary and involuntary processes. Biases in

memory are most reliable in studies of depression and negative mood, although comparable anxiety effects are also documented. Depressed individuals tend to show enhanced recall for negative events or stimuli at the expense of positive events. These effects seem most reliable when the test of memory is explicit rather than implicit and when some active processing of the memorized material is required. Various other tasks, including judgment and decision making, also show cognitive bias. From the self-regulative perspective, distress may relate to the extent to which the person balances the goal of maintaining awareness of threat against a focus on the immediate task at hand.

Clinical Disorder

Distress is a central symptom of both mood and anxiety disorders. A simple view of clinical distress is that it represents the upper extreme of a continuum of vulnerability to negative emotion. However, clinical disorder involves qualitative abnormalities of behavior in addition to distress, such as avoidance of challenging situations, self-harm, and difficulties in social interaction. Distress in clinical depression and anxiety is bound up with problems in behavioral adaptation to everyday life. Self-regulative approaches to understanding distress contribute to understanding the maladaptive nature of these disorders. Central to both anxiety and depression are stable but false negative beliefs about the self, which may be represented as schemas. The anxious person believes him- or herself to be especially vulnerable to threats of certain kinds, whereas the depressed patient experiences cognitions of lack of self-worth and hopelessness. Cognitions and behaviors differ across clinical conditions, but, in general, unrealistic negative self-beliefs feed into the faulty appraisal of the person's place in the external world, choice of ineffective coping strategies such as worry, and consequent distress.

The view of distress as a sign of maladaptive self-regulation has implications for therapy. In mild sub-clinical distress conditions, it may be sufficient for individuals to learn specific coping skills that permit them to manage the specific situations that provoke distress. For example, individuals with mild social anxiety may be helped by explicit instruction in social skills. Distress is alleviated both through individuals' increased confidence and positive self-appraisal and through the likelihood that the individuals' greater skill will lead to more positive outcomes in the problematic situation. In more severe cases, stress management techniques such as skills training fail to address the underlying cognitive distortions that drive both distress and behavioral problems. Cognitive-behavior therapy seeks to uncover and modify faulty cognitions through a variety of techniques.

Empirical studies show that clinical improvement in behavior and affect is accompanied by a decline in cognitive bias.

Divorce-Related Stressors

Mental Health Consequences

Risk and Resilience

Implications for Prevention

Glossary

<i>Effect size</i>	A statistical indicator, expressed in standard deviation units, of the magnitude of the relation between two variables.
<i>Externalizing</i>	A constellation of psychological symptoms indicative of acting-out behavior, such as aggression and conduct problems.
<i>Internalizing</i>	A constellation of psychological symptoms experienced internally, such as depression and anxiety.
<i>Meta-analysis</i>	A quantitative method of literature review in which measures of central tendency (e.g., the mean) and variation are obtained for outcomes examined across multiple studies.
<i>Moderator</i>	A variable that affects the direction and/or strength of the relation between an independent or predictor variable (e.g., divorce) and a dependent or criterion variable (children's mental health problems).

Divorce-Related Stressors

Parental divorce has become a common experience for children, particularly in the United States, where divorce is more common than in any other developed country. The rate of divorce in the United States has increased over the course of the twentieth century, with a particularly rapid rise beginning in the decades of the 1960s and 1970s followed by a modest decline at the close of the century. Currently, close to half of all marriages end in divorce, affecting approximately 1.5 million children a year. Although divorce rates vary among families of different demographic profiles, between 30 and 40% of all children are expected to live in a divorced, single-parent home by the age of 16.

Parental divorce is not a singular event. Rather, it marks a multitude of potential stressful changes and disruptions in children's social and physical environments that occur before, during, and after parental separation. For example, interparental conflict often begins many months and/or years prior to separation, can escalate around separation and/or divorce, and can continue well after separation as parents negotiate new parenting-related issues such as child custody, visitation arrangements, and child support. As in the case of interparental conflict, many of the stressful changes and experiences faced by children from divorced families occur in the family domain, involve interpersonal loss and/or conflict, and are not easily controllable by children.

Several of these changes occur in children's relationships with parents. Despite an increasing emphasis on joint custody in many states, over 80% of children from divorced families still reside primarily with their mothers. Consequently, parental separation often means the loss of daily contact with fathers. Moreover, for most children contact with non-custodial fathers becomes increasingly infrequent

over time. Children with continued father involvement may face the challenge of residing in two households, with different rules and discipline practices. The quality of relationship between fathers and children may also change following divorce, as fathers try to adapt to a parenting role when they do not reside with their children. Considerable research indicates that a positive relationship, including warm and supportive interactions as well as appropriate discipline, is an important factor affecting children's well-being following divorce.

Children's relationships with their mothers also change. Custodial mothers report high levels of stress as they negotiate the dual task of adjusting to the dissolution of marriage as well as to a new lifestyle with increased responsibilities. Juggling single parenthood, work-related demands, legal matters, and the re-negotiation of social relationships places custodial mothers at increased risk for psychological distress and physical illness. Maternal stress and distress, in turn, have been linked to disruptions in parenting behavior. Following divorce, many custodial mothers are less supportive, affectionate, and consistent in their discipline practices and engage in more conflict with children.

Many newly divorced families also face financial stress. Both mothers and fathers may experience a decline in standard of living following divorce. Income loss can result in potentially stressful changes for children, including moving to a different home, changing neighborhoods, and changing schools. While these transitions involve the loss of material possessions, children also face the loss of friends, teachers, and other important members of their social support networks.

When asked about the various changes that arise following divorce, children, parents, and clinicians who work with children from divorced families agreed that the most stressful experiences children face occur in the nuclear family domain. These include being blamed for the divorce, verbal and/or physical interparental conflict, and derogation of one parent by another. Other experiences perceived as highly stressful by children include derogation of parents by relatives or neighbors, having to give up possessions, and maternal psychological distress.

For many children, parental divorce is the first of several family transitions, each of which brings a new set of stressful changes. Forty percent of divorced couples remarry before their youngest child reaches age 18. Given that remarriages are also more likely than first marriages to end in divorce, a sizeable number of children face multiple family transitions over the course of their childhood. Although

remarriage can improve the financial and emotional support provided to parents, it requires complex family reconfiguration. For children, this includes the addition of a stepparent, as well as other stepkin relations such as stepsiblings, grandparents, and other extended family members. When additional children are born into the family following remarriage, half-sibling relationships are created. The incorporation of new family members alters family dynamics, including relationships with biological parents. In addition, children may face physical transitions such as an additional residential move or sharing of a room with other children.

Mental Health Consequences

The findings from five decades of empirical research have consistently demonstrated that children from divorced families are at increased risk for adjustment or mental health problems relative to children from continuously married families. When this body of literature is summarized using meta-analysis, the effect sizes are small to moderate, with the largest group difference occurring in the domain of externalizing problems or conduct problems. Children from divorced homes, on average, engage in more misbehavior, are more aggressive, and/or have higher rates of delinquency. Children from divorced homes also show greater difficulties in the areas of psychological adjustment (i.e., depression, anxiety, happiness), social adjustment, self-concept, and school achievement.

The small to moderate effect sizes have caused some researchers to question the significance of parental divorce as a risk factor for adjustment problems. However, there are several reasons why divorce should be considered an important risk factor with significant population-level implications. First, given the high prevalence of divorce in society, small to moderate effects on child maladjustment have a substantial impact on population rates of problem outcomes for children from divorced families. Second, trends in studies from the 1990s show that effect sizes have increased from the 1980s. Third, a sizeable subset of children from divorced families have significant mental health problems. Approximately 20–35% of children from divorced families experience clinically significant mental health problems, a rate at least twice that of children from two-parent families. Fourth, adolescents from divorced homes engage in more high-risk behavior with potentially long-ranging consequences. Adolescents from divorced homes are more likely than those from two-parent homes, for example, to drop out of school, become

sexually active or pregnant at an earlier age, and use drugs or alcohol.

Finally, the effects of divorce for many children and adolescents are not transitory. Longitudinal studies indicate that children from divorced families are at elevated risk for difficulties several years after parental separation, with problems continuing throughout adulthood. Across studies, adults who experienced divorce in childhood or adolescence have been found to function more poorly on a range of indicators including depression, life satisfaction, marital quality, educational attainment, income, occupational prestige, and health outcomes such as illness and mortality. Adults who experienced divorce as children or adolescents are also more likely to divorce themselves. Researchers have speculated that these long-term consequences are the result of disruptions in normal development during childhood and adolescence.

Risk and Resilience

Although children from divorced families are at elevated risk for adjustment problems, there is tremendous variability in response. The majority of children in divorced families show no adverse effects relative to children raised by continuously married families. Thus, research on children from divorced families has shifted over time from examining the mental health and adjustment consequences of divorce toward understanding why some children are more adversely affected by divorce than others. Researchers have identified several risk and protective factors that act as moderators between divorce and children's mental health, including stress, parent-child relationships, and child characteristics.

Exposure to Stressors

Greater exposure to stressful divorce-related stressors is associated with increased mental health problems among children. The frequency of divorce-related changes faced by children and families, as assessed by divorce events checklists, relates positively to difficulties in the domains of internalizing and externalizing symptoms, self-concept, and social and academic competence. Children exposed to more divorce-related stressors also show maladaptive cognitions, including a reduced sense of their ability to affect their environments.

Studies have also examined the relations between specific types of divorce stressors and children's mental health. More limited post-divorce economic resources have been consistently related to increased maladjustment. Exposure to interparental conflict

is one of the most potent determinants of children's post-divorce adjustment problems. A positive association between intense marital conflict and child mental health problems has been well documented. Researchers increasingly believe that children in families marked by intense, chronic marital conflict and/or violence may be better off in the long run if their parents divorce and the degree of conflict is reduced (although a decrease in conflict does not always occur). Interestingly, in divorcing families in which overt conflict was very low or absent prior to separation, children are also at risk for poor adjustment, perhaps due to the unexpected nature of the dissolution. In either scenario, post-divorce conflict that involves putting a child in the middle by, for example, one parent denigrating the other parent or asking the child to carry hostile messages, is associated with higher levels of child depression and anxiety.

Parent-Child Relationships

The degree to which the quality of children's relationships with their parents is disrupted following divorce is predictive of adjustment problems. Children whose custodial mothers provide high levels of warmth, affection, and effective, consistent discipline following divorce exhibit fewer behavior problems, higher self-esteem, and better academic performance than children with low-quality mother-child relationships. Experimental research has shown that intervention-induced increases in maternal warmth and effective discipline mediate program effects to reduce children's mental health problems. Moreover, high-quality mother-child relationships serve as a buffer, mitigating the negative effects of divorce-related stressors on children's adjustment problems.

Because fathers are more likely to be noncustodial parents, research initially focused upon whether the amount of father-child contact affected children's adjustment after divorce. Findings from this line of research were inconclusive. It is now understood that it is the quality and not quantity of father-child contact that is important to divorce adaptation. High-quality father-child relationships are related to better child post-divorce adjustment than low-quality relationships.

Child Characteristics

Research examining the association between child demographics, such as age and gender, and post-divorce adjustment has revealed few consistent findings. Although some studies, particularly older studies or those examining conduct problems, indicate less advantageous outcomes for boys relative to girls,

meta-analyses show that divorce is associated with a range of poor outcomes for both boys and girls. Similarly, while meta-analysis has also shown that children in middle childhood and adolescence appear to be more negatively impacted by divorce than pre-schoolers or college students, far fewer studies have examined divorce adjustment in these latter two age groups, making it difficult to draw firm conclusions regarding the effect of age on children's adaptation to divorce.

Recently, a body of literature has begun to emerge that shows that the manner in which children interpret and cope with divorce-related stressors has implications for their adjustment. Children who lack an internal sense of control over their environment or who have a tendency to interpret divorce-related stressors in a characteristically negative style or as threatening to their well-being are more likely to experience post-divorce adjustment problems. Also, children who use positive cognitive or behavioral coping strategies, such as active problem solving or positive cognitive restructuring, experience fewer psychological adjustment problems than children who employ avoidant coping strategies. Theoretically, researchers agree that the adaptive value of specific coping strategies depends on context. Children may benefit most, for example, by cognitively reframing a situation that is largely outside of their control, while problem solving may be an adaptive strategy for situations that are more controllable. There is also growing evidence that the effects of using appropriate coping strategies may be mediated by increasing children's sense of efficacy to deal with the problems they encounter in their lives.

Children's temperament, which theoretically modulates the expression of activity, emotionality, reactivity, and behavior, has also been implicated as important to children's post-divorce adjustment, although this area of research is currently small. Findings indicate, for example, that children rated as more emotionally reactive are at increased risk for maladjustment compared to children who are less reactive and that this effect may be mediated by leading to an increase in negative appraisals of the threat involved in stressful situations.

There is also evidence that the effects of parent and environmental factors are not independent of child factors, but rather are mediated through their effects on children's beliefs about their relations to the world and their ability to cope. For example, the effects of poor parenting quality on children's mental health appears to be partially mediated by increasing children's fears that they will not be cared for by anyone. Similarly, the effects of interparental conflict (a stressor over which children have little control) on

children's mental health is in part mediated by decreasing children's coping efficacy beliefs.

Implications for Prevention

Efforts to facilitate adaptation to divorce and prevent maladjustment have focused on altering modifiable contextual, family, and/or child variables demonstrated to affect children's divorce adjustment. The most widely available preventive interventions are child-focused programs that are often provided in school settings. Such interventions generally seek to increase children's accurate understanding of divorce and teach new skills for coping with divorce-related stressors. Preventive programs that target custodial parents focus on teaching effective parenting skills to enhance the quality of parent-child relationships and help parents shield children from stressful experiences such as interparental conflict. Among programs that have been rigorously evaluated using experimental and/or quasi-experimental trials, results have been positive. Child-focused programs have been successful in improving child mental health outcomes, including internalizing and externalizing symptoms, with program effects still present at follow-up studies 1 to 2 years later. Similarly, prevention programs for custodial mothers have been successful in improving the quality of the mother-child relationship, effective discipline, and child mental health outcomes. Recent evidence shows that program effects last well into adolescence, leading to reductions in mental health problems, drug and alcohol use, school failure, and risky sexual behavior and improvements in academic performance and competence.

Description

Consequences

Remediation Strategies

Historical Perspectives

Glossary

<i>Domestic violence</i>	Any act of maltreatment occurring in the home environment of the victim perpetrated by a person who assumes the role of a caregiver or who is in an established relationship with the victim.
<i>Neglect</i>	The omission of appropriate caretaking functions that leads to a lack of self-preservation and growth in the dependent individual.
<i>Physical abuse</i>	A harmful act carried out on an individual with the intention of causing physical pain or injury.
<i>Sexual abuse</i>	Illegal, nonconsensual, or socially inappropriate contact or exposure of genitalia.
<i>Verbal/emotional/mental abuse</i>	The use of derogatory statements that cause the victim psychological pain or feelings of devaluation.

Description

Domestic violence includes all aspects of abuse and neglect that are perpetrated within the victim's home environment by a person who assumes the role of a caregiver or who is in an established relationship with the victim. Abuse and neglect have been around since the beginning of civilization; however, various forms of abuse have only recently been defined and studied extensively. Although definitions of abuse vary considerably, neglect and three types of abuse (physical abuse, sexual abuse, and psychological/mental/emotional/verbal abuse) have consistently been recognized in the domestic violence literature. This article provides an overview of domestic violence, including its risk factors, its prevalence, and a delineation of neglect and abuse.

Neglect

In general, neglect refers to the omission of appropriate caretaking functions that results in harm to the dependent individual. Victims of neglect are therefore dependent on a guardian or caregiver for self-preservation and growth. Most often, victims of neglect include children, adults who evidence severe mental or physical disabilities (e.g., mental retardation and Parkinson's disease), and elderly people with medical complications or other problems associated with old age. Prevalence studies consistently indicate that neglect is the most frequently occurring form of maltreatment. For instance, the National Clearinghouse on Child Abuse

and Neglect reported that an estimated 906,000 children were determined to be victims of child abuse in 2003 and that, of those claims, more than 60% experienced neglect. Although risk factors are varied, they most often include substance abuse, physical disabilities, social isolation, psychiatric illness, social isolation, stress, poor parenting skills, and unrealistic expectations of the child's development. People of lower economic status appear to be overrepresented in abuse samples, perhaps because abuse is more common for these individuals but also because they may be reported and charged with abuse more often due to reasons associated with poverty (e.g., relatively inadequate representation by legal counsel). Incidents of neglect include interfering with (or delaying) medical protocol, leaving small children unattended for extended periods of time in potentially dangerous situations (e.g., being left in an automobile while the caregiver drinks alcohol inside a bar), restricting or failing to provide sufficient nutrients or shelter, failing to repair home hazards (e.g., exposed electrical wires and broken steps), exposing victim to toxins or bacteria (e.g., failing to clean dog feces from the kitchen floor where an infant crawls), failing to provide adequate affection, and restricting children from attending school. Indicators of neglect include dirty and unkempt bodies, rotten teeth, clothes that are too small or are in need of repair, and untidy and disheveled home environments.

Psychological Abuse

Psychological abuse, also known as verbal, mental, or emotional abuse, typically refers to derogatory statements that cause harm to or interfere with the psychological adjustment of the victim. These statements are most often attacks on the victim's competence ("You can't do anything right; you're just a big dummy") or character (e.g., "You're a lazy, unpopular, good for nothing"). Psychological abuse is usually associated with obscenities, negative voice tones, exploitation, encouraging corruption and delinquent behavior, excessive teasing, harmful threats, ridicule, or derogatory statements about the victim or people whom the victim likes. There do not appear to be significant gender differences regarding the prevalence of psychological abuse because studies have consistently indicated that the vast majority of the population has experienced some level of psychological abuse from an adult family member in their lifetime. Interestingly, people often underestimate the severity of psychological abuse relative to other forms of maltreatment because its consequences are subtle and there are few, if any, legal sanctions that

mitigate against its use. Nevertheless, severe consequences of verbal abuse have been found, including depression, antisocial behaviors, low self-esteem, intellectual deficits, academic difficulties, health problems, shyness, problem-solving deficits, anxiety, and difficulties with conflict resolution and other social skills. Moreover, psychological abuse is often a precursor of physical abuse by the perpetrator and of retaliatory aggression by the victim.

Physical Abuse

Physical abuse is usually defined as any harmful act carried out on an individual with the intention of causing pain or injury (e.g., kicking, spanking severe enough to cause bruises, whipping with an extension cord, punching, biting, or threatening with a knife or a gun). Victims are usually people who are emotionally or financially dependent on the perpetrator (e.g., spouses, lovers, children, or the elderly). Although neglect is estimated to be the most frequently occurring form of maltreatment, physical abuse has probably received greater attention in the scientific literature. According to a 1998 Commonwealth Fund Survey, approximately 3 million women are physically abused each year by their intimate companions, sometimes resulting in fatalities. In 2003, the Bureau of Justice Statistics Crime data indicated that, on average, more than three women are murdered by their husbands or boyfriends each day in the United States. Approximately one-half of the adult victims of physical abuse retaliate with physical violence of their own due to self-defense or escalation of violence, lending support to the notion that physical abuse in adults is often reciprocal. Indeed, males in dependent relationships also suffer from physical abuse; however, it is relatively less often reported to authorities and the maltreatment is usually not as severe. Interestingly, the prevalence rates of physical abuse among homosexual adult relationships approximate those of heterosexual adult relationships.

Children are prime targets for physical abuse. Indeed, estimates of physical-abuse victimization in children are usually around 30%. The perpetrators of child physical abuse are often of lower economic status, substance abusers, single parents, socially isolated, and depressed; evince inadequate coping skills; and report a history of being maltreated as a child. Other risk factors include low birth weight, physical and mental disabilities, immaturity, child noncompliance and misconduct, impulsiveness, deficits in family cohesion, family conflict, history of abuse, limited positive interactions, unrealistic expectations and negative perceptions of children, inconsistent

parenting styles, lack of familiarity with the developmental norms of children, stress, lack of empathy, and antisocial personality. The number of studies conducted with elderly victims of physical abuse and other forms of maltreatment has recently increased, more so than in other age groups. Although this increased attention is due to multiple factors, several are fairly obvious. The human life span has increased, resulting in more elderly individuals who are living with age-associated medical problems and physical limitations. Changes in health care, among other factors, have forced older adults to reside with family who are often ill-equipped to tolerate the added stress associated with their care, which often results in frustration for both the victim and perpetrator. A recent study of nursing home residents revealed that aggression from residents toward the staff was the strongest predictor of elder abuse. Investigations of the risk factors for elderly abuse are consonant with those of other age groups.

Sexual Abuse

Sexual abuse is generally defined as any illegal, non-consensual, or inappropriate contact or exposure of genitalia, including sexual humiliation. However, legal definitions of sexual abuse vary considerably. For instance, some agencies (i.e., Federal Bureau of Investigation) have defined rape as attempted or completed vaginal intercourse with a female by force and against her will, whereas states have adopted unique qualifiers for this term, such as gender neutrality; anal or oral penetration; insertion of objects; and being unable to give sexual consent because of mental illness, mental retardation, or intoxication. Other common patterns of sexual abuse include, but are not limited to, being forced to observe or perform pornography and fondling or kissing the genitalia of a child or nonconsenting adult. Approximately 10% of marriages have involved rape without physical violence, and estimates from the National Clearinghouse on Child Abuse and Neglect have indicated that as much as 10% of reported abuse cases in the United States involved inappropriate sexual contact or exposure. Sexual abuse victimization may occur as early as infancy, and it is characteristically progressive; approximately half of sexually abused children will continue to be abused until they leave the abusive home. The perpetrators of domestic sexual abuse are very often in-laws, foster parents, nonrelatives, older siblings, or cousins, but they may also include other relatives living in the home of the victim. The majority of perpetrators of sexual abuse are male. However, female perpetrators may be more common than studies suggest, perhaps because their abuse is

not reported more often than that of males. A large percentage of rapes in college populations are committed by someone the victim knows. Factors that have been found to influence sexual abuse include neurological disorders, particularly frontal lobe abnormalities; sexual abuse of or repeated witnessing of pornography by the perpetrator during childhood; mental illness; substance abuse; and dysfunctional family systems.

Consequences

The consequences of abuse and neglect are, as might be inferred, extremely debilitating for the victim, and these negative consequences inevitably affect close relatives and friends of the victim. Consequences that have been identified include low self-worth, anxiety and mood disorders, problems maintaining pleasant functional relationships, problems in toileting, antisocial conduct and maltreatment of others, suicide, poor social and coping skills, problems in school or employment, substance abuse, and personality disorders. Malnutrition is a hallmark of neglect. Sexual abuse victims may demonstrate inappropriate or promiscuous sexual activity, including prostitution and other illegal sexual undertakings. A particular concern is the recapitulation of abuse because, more often than not, the victim becomes a perpetrator with the passage of time.

Remediation Strategies

Professionals (i.e., teachers, police officers, ministers, and health-care workers) are mandated in most states to report suspected incidents of domestic violence. Familiarity with the risk factors and consequences of domestic violence are of great assistance in the identification of abuse. However, professionals are often not trained, or able, to recognize abuse, particularly because victims are motivated to deny or minimize assaultive behaviors because their perpetrators are usually people whom they often love, fear, or respect. Moreover, once identified, domestic violence is difficult to remediate. Initial strategies focus on assessing the victim's environment to determine if it is (1) safe for the victim to remain in the home with the perpetrator, (2) necessary to remove the victim from the home (to live with other relative, in a foster-care home, or in a shelter), or (3) necessary to mandate that the perpetrator leave the home. The separation of the victim from the perpetrator is certainly the safest strategy for terminating the abuse. However, this approach is often not possible because relatives are frequently unavailable and shelters and

foster-care homes usually operate with inadequate funding, causing them to sometimes be full, dangerous, or overcrowded. Moreover, familial separation is marked with changes that bring about stress (e.g., new school placements, feelings of abandonment and rejection, and financial losses). Therefore, separation is typically sought only when cases of maltreatment are severe (e.g., sexual abuse or repeated instances of physical abuse). Adult victims and perpetrators of domestic violence are usually forced to fund their own therapy. However, state child protective service agencies will provide psychologically based intervention for child victims and relevant family members at no cost, when indicated. Interventions may be focused on reunifying and improving the function of the existing family system or facilitating a comfortable and healthy transition for the victim without the perpetrator. Therapy is ordinarily mandated by the legal system for child victims and their perpetrators when the goal is family reunification.

Of the interventions that have been evaluated, the cognitive-behavioral and stress-reduction strategies appear to be most promising. Cognitive-behavioral interventions most often include the recognition of the early signs of abuse, learning strategies to improve safety and prevent the escalation of abuse, restructuring faulty cognitions and beliefs about the abuse (e.g., victims may blame themselves for abuse; perpetrators might think the role of a woman is to serve her spouse), learning to improve appropriate social/assertion skills, anger-management skills training, contingency contracting (obtaining rewards that are contingent on behavioral improvement, e.g., good grades in school, compliance to the directives of parents, and making statements of affection), learning to eliminate home hazards and improve home beautification, behavioral substance-abuse counseling (e.g., controlling urges to use substances, restructuring the environment so that drug use is less likely, and contingency contracting), vocational skills training, learning positive parenting techniques (e.g., reinforcing the child for desired behaviors, positive practice, and learning about child development and nutrition), marital counseling, multisystemic family therapy, and communication skills training. Stress-management strategies include bringing children to day care or babysitters to allow the caregiver a relaxing break at home, learning problem-solving and coping skills, attending Parents Anonymous groups (an organization established to support the victims and perpetrators of abuse), planning pleasant activities with the family, and encouraging/facilitating participation in community groups (e.g., church and boys' and girls' clubs).

Historical Perspectives

Perceptions of domestic violence have changed markedly throughout history and across cultures. Indeed, it was not until the past century that laws were initiated to protect children and wives from being beaten by their parents and husbands; for instance, as recently as 1968 many states did not mandate professionals to report their knowledge of abusive treatment to abuse registries. Nevertheless, there have been radical improvements in public sentiment and the legal system regarding the eradication of domestic violence. In ancient times, individuals with mental and physical disabilities were scorned or killed to rid the state and parents of the economic burden of caring for them. Although the treatment of children and women improved somewhat in most societies during the Middle Ages, neglect, ridicule, slavery, and harsh physical punishment continued. It is also interesting to note that children in nineteenth-century industrialized nations were forced to work up to 14 h a day in hazardous conditions.

The improvements in the rights of children and women were partially a result of humanitarians who wrote books about the injustice of domestic violence. For instance, during the Renaissance Thomas Phaire wrote a book addressing the problems of children called *The Book of Chyldren*, and in the late 1600s and early 1700s Locke and Rousseau wrote books that mentioned issues pertaining to the development of children. Erin Pizzey's 1974 book *Scream Quietly or the Neighbors Will Hear* was one of the first manuscripts in the literature that specifically addressed remediation procedures for spousal abuse.

National organizations, governmental meetings, and activists also influenced the passing of laws protecting against domestic violence. The Society for the Prevention of Cruelty to Children in the late 1800s was formed to protect rights and welfare of children. In 1909, President Theodore Roosevelt organized the first meeting in the White House on children's welfare, which supported the Children's Bureau in 1912 to protect the welfare and rights of children. Pizzey was responsible for developing the first refuge for female victims of spousal abuse in England in 1971; the first refuge for women and their children in the United States was initiated by the Women's Advocates in 1972.

Although domestic violence continues today at relatively high rates, research and public opinion and protection laws against domestic violence are at their highest level of sophistication. Indeed, all 50 states currently require professionals to report suspected instances of child maltreatment, and most states

have explicitly allocated significant funding to programs for the prevention and treatment of domestic violence. Indeed, law enforcement personnel now routinely receive specialized training for managing situations involving domestic violence, including victim-sensitivity training. Violence treatment programs have also become increasingly more evidence-based while addressing contemporary issues such as violence among same-sex couples, date rape, violence prevention within school settings, and comorbid conditions (e.g., substance abuse).

Glossary

<i>Agonist</i>	A drug that mimics the actions of a neurotransmitter at its receptor.
<i>Antagonist</i>	A drug that blocks the actions of a neurotransmitter at its receptor.
<i>Catecholamine</i>	A chemical containing a catechol nucleus (a benzene ring with two adjacent hydroxyl groups) and an amine group.
<i>Central nervous system (CNS)</i>	A general term referring to the entire brain and spinal cord.
<i>Dopamine (DA)</i>	A catecholamine used as a neurotransmitter in the central nervous system; also known as dihydroxyphenylethylamine.

Hypothalamic-pituitary-adrenocortical (HPA) axis
Mesencephalon

A principle component of the stress response that regulates the secretion of glucocorticoid hormones from the adrenal gland.

The midbrain; many DA cells have their soma, or cell bodies, located in two regions of the mesencephalon, the substantia nigra (SN) and the ventral tegmental area (VTA).

Neuron/nerve

The fundamental cellular unit of the nervous system.

Neurotransmitter

A chemical released by a neuron at a synapse to provide a signal to another neuron.

Nucleus accumbens (NAC)

A subcortical brain region thought to be an important interface for motivation and motor outputs; it consists of two subregions, the core and the shell.

Prefrontal cortex

A cortical region located towards the front of the brain involved in planning and other cognitive functions; it receives a dopaminergic input from the ventral tegmental area and projects to the striatum and nucleus accumbens.

Striatum (or neostriatum)

A region of the basal ganglia that is important for movement; the striatum receives a dopaminergic projection from the substantia nigra.

Synapse

A specialized contact zone that is the site of chemical communication between neurons.

Tyrosine hydroxylase (TH)

The rate-limiting enzyme in the synthesis of dopamine; it converts the amino acid tyrosine to dihydroxyphenylalanine (DOPA).

Dopamine is a chemical transmitter in the central nervous system, where it acts to modulate the actions of other neural signaling molecules. Physical or psychological stress results in an activation of nearly all neurons that use dopamine as their transmitter, causing an increase in dopamine release. Those dopamine neurons projecting from the mesencephalon to the prefrontal cortex are particularly sensitive to such stress. The mechanisms by which dopamine release is increased in response to stress appear to include (1) an increase in the firing rate of the dopamine neurons, (2) changes in the inputs to the dopamine terminals from adjacent cells, and (3) an increase in the activity of tyrosine hydroxylase, the rate-limiting enzyme in dopamine synthesis. The precise roles that these changes in dopaminergic neurotransmission play in the generation of stress and/or coping responses are not yet clear. However, the study of these mechanisms in animal models may lead to a more complete understanding of the biological basis of a number of psychiatric disorders.

Introduction to Nerve Cells and Synaptic Transmission

Nerve cells, or neurons, are the elementary signaling units within the nervous system. The highly complex behaviors of humans and other animals result from

the specific interconnections of a vast number of these neurons. Neurons have four main regions: (1) the dendrites, which receive most of the information coming into the neuron, (2) the cell body, or soma, which processes that information and also contains the mechanisms of protein synthesis, (3) the axon, which carries an electrical signal called an action potential from the cell body to the nerve terminal, and (4) the terminal, which can respond to signals received from the axon and from adjacent neurons by releasing a chemical transmitter. Neurons communicate with one another through minute gaps between them known as synapses. The chemical transmitters released by the presynaptic terminal of a neuron diffuse across this synaptic space to act on specialized receptors on the dendrites and/or cell body of a neighboring postsynaptic neuron (Figure 1).

Overview of Dopaminergic Pathways in the Central Nervous System

The nervous system uses many different transmitters, each with different functional characteristics. However, they can be broadly divided into two groups. The first contains the fast-acting transmitters that provide primary information. Many of the neurons that use acetylcholine or the amino acids glutamate and γ -aminobutyric acid (GABA) fall into this

Figure 1 Schematic representation of the life cycle of dopamine. Upon accumulation of tyrosine (Tyr) by the neuron, tyrosine is sequentially metabolized by tyrosine hydroxylase (TH) and aromatic acid decarboxylase (AADC) to dopamine (DA). DA is then accumulated into vesicles by the vesicular transporter, where it is poised for release and protected from degradation. Once DA is released, it can interact with postsynaptic dopaminergic receptors or different types of presynaptic autoreceptors that regulate transmitter release, synthesis, or firing rate. The accumulation of DA by the high-affinity membrane DA transporter (DAT) terminates the extracellular actions of DA. Once accumulated by the neuron, DA can be metabolized to inactive species by key degradative enzymes such as monoamine oxidase (MAO) or taken back up by the vesicular transporter.

category. The second group is composed of the more slowly acting transmitters that have a modulatory influence on the actions of the first group. Dopamine (DA) is an important member of this second, modulatory group of transmitters. DA has been implicated in a variety of functions including motor control, cognition, endocrine regulation, emotion, and cardiovascular regulation. Abnormalities in DA systems can lead to major neurological and psychiatric dysfunction.

DA is a catecholamine, a term that refers to its biochemical structure. Other catecholamines include norepinephrine (NE) and epinephrine, also known as adrenaline. DA is synthesized from tyrosine through the actions of two enzymes. First, tyrosine hydroxylase (TH), the rate-limiting enzyme in the process, converts L-tyrosine to dihydroxy-L-phenylalanine (L-DOPA). Then, aromatic acid decarboxylase (also known as DOPA decarboxylase) immediately converts L-DOPA to DA (Figure 1). In some cells, DA is further converted to the neurotransmitter NE or even further to epinephrine, but in many neurons DA itself serves as an active neurotransmitter.

The rate at which DA is synthesized can be controlled in many ways. DA can inhibit tyrosine hydroxylase (TH), a process termed end-product inhibition. Additional influences can be exerted by changes in the number or structure of the TH molecules or by changes in the availability of necessary cofactors for tyrosine hydroxylation. Because of these regulatory processes, neurons are usually able to match the rate of DA synthesis to the rate of DA utilization, thereby avoiding either the build up or the depletion of the transmitter.

DA release occurs in response to an influx of calcium into the nerve terminal, which is triggered by the arrival of an action potential. Like DA synthesis, DA release is regulated by several processes. For example, DA can act back on the terminal from which it was released to inhibit subsequent release. Such influences represent negative feedback loops and act to keep the rate of DA utilization within relatively narrow limits.

DA induces a wide range of cellular and biochemical effects in neurons by way of its actions on its specific postsynaptic receptor proteins. These effects include relatively rapid (seconds) modulation of biochemical events in the target cell resulting in changes in the responsiveness of the cell to other neuronal inputs, as well as more gradual (minutes to hours) alterations in gene expression. The sensitivity of a target cell to DA is regulated: a period during which DA release is reduced causes an increase in the number of postsynaptic receptors and thus a supersensitivity of the neuron to DA, whereas an excess of DA leads to a decrease in receptors and in the sensitivity

of the target. Intracellular components of signal transduction responses are also actively regulated in the brain, providing many potential mechanisms by which signaling can be altered.

The neurotransmitter actions of released DA are terminated by diffusion from the receptor site. It can then be transported into presynaptic terminals by high-affinity uptake sites. Once taken up, DA can be metabolized in the nerve terminal by the monoamine oxidase (MAO) to dihydroxyphenylacetic acid (DOPAC) or further sequestered into storage vesicles for later reuse. Released DA can also be metabolized extraneuronally by catechol-O-methyltransferase (COMT) to 3-methoxytyramine (3-MT). The product of MAO plus COMT is homovanillic acid (HVA).

There are several major dopaminergic pathways (Figure 2). The two main mesencephalic regions containing DA cell bodies are the substantia nigra (SN) and ventral tegmental area (VTA). Axons of the DA cells in the SN form the nigrostriatal projection and provide the dopaminergic innervation of the caudate and putamen, or striatum. This region is part of the basal ganglia, a group of nuclei involved in motor and cognitive functions. Degeneration of the nigrostriatal DA neurons is the principal cause of Parkinson's disease.

The mesolimbic and mesocortical DA systems arise from the VTA, which is located just medially to the SN. The mesolimbic DA system innervates subcortical regions such as the nucleus accumbens (NAC), olfactory tubercle, and amygdala. The mesocortical system provides dopaminergic afferents to prefrontal, anterior cingulate, and entorhinal cortex. Disruption of dopaminergic neurotransmission in these areas has been associated with neuropsychiatric illnesses such as schizophrenia. The tuberoinfundibular DA

Figure 2 Schematic illustrating some of the major dopaminergic neurons and their projection areas in the rodent. The mesocortical limbic pathway is illustrated in red, nigrostriatal tract in green, and tuberoinfundibular in blue. Abbreviations: ACC, anterior cingulate cortex; ME, median eminence; NAC, nucleus accumbens; OT, olfactory tubercle; PFC, prefrontal cortex; SN, substantia nigra; STR, striatum; VTA, ventral tegmental area.

system is another important dopaminergic pathway; it connects the hypothalamus and pituitary gland. These DA neurons are important in the regulation of the hormone prolactin from the anterior pituitary.

Responses of Dopaminergic Systems to Acute Stressful Stimuli

Most antidepressant drugs have direct pharmacological effects on catecholamine neurotransmission. Tricyclic antidepressants, for example, block the uptake of DA and other catecholamines, thus increasing the biochemical effects of these neurotransmitters. Based on the rationale that people suffering from anxiety and depressive disorders may have dysfunctions of brain catecholamine systems, changes in dopaminergic activity in response to stressful stimuli have been studied in a number of animal models. Some interesting effects have been observed, as is described below. However, it must also be emphasized that nearly all antidepressant drugs have very prominent effects on NE and serotonin (5-hydroxytryptamine, 5-HT) systems, and it is clear that multiple neurotransmitter systems are involved in the pathophysiology of stress disorders and depression.

Rodent models of environmental stress include tail pinch and/or shock, immobilization, forced swim, exposure to cold, foot shock, and social defeat. These stress-inducing procedures produce heterogeneous effects on the various dopaminergic projection systems. For example, the activity of tuberoinfundibular DA neurons is decreased by stressful stimuli, which results in an increase in plasma prolactin levels. This increase in prolactin likely plays a role in stress-induced activation of the immune system.

In contrast to the tuberoinfundibular DA neurons, the dopaminergic neurons that ascend from the midbrain are activated by stress. Mesocortical DA neurons projecting from the VTA to the prefrontal cortex appear to be particularly sensitive to acute stress so that relatively mild stressors lead to pronounced activation of DA neurotransmission in the prefrontal cortex. Stress-induced activation of DA neurotransmission also occurs in the mesolimbic and nigrostriatal pathways, but to lesser extents than in the prefrontal cortex. Further heterogeneity is observed within the mesolimbic projections to the NAC. Stressors appear to activate dopaminergic activity to a greater extent in the NAC_{shell} (the limbic NAC) subregion than in the NAC_{core} (the motor NAC) and in the striatum.

Consistent with these differences in activation of DA terminal regions, it has been observed that VTA neurons increase their rate of firing during stress, but SN neurons respond only briefly if at all.

Moreover, acute exposure to stress has been shown to increase TH activity in DA terminal regions, and the rank order of this effect is identical to that of the neurochemical measurements (prefrontal cortex > nucleus accumbens > striatum). Behavioral stress also induces neuroadaptations in dopaminergic neurons that are very similar to those induced by drugs of abuse.

Collectively, these data demonstrate that increases in DA neurotransmission occur during exposure to acute stress. But what functional significance do these changes in DA activity represent? There are several lines of evidence suggesting that DA systems play critical roles in stress responses. First, anti-anxiety drugs such as benzodiazepines can reduce stress-induced increases in DA release, suggesting that the therapeutic actions of these compounds may be due at least in part to reversing increased dopaminergic activation. Second, lesions of midbrain DA neurons lead to a partial suppression of endocrine stress responses (see “Dopamine and the HPA Axis” for a more complete discussion). Third, enhancement of DA signaling in the amygdala attenuates stress-induced ulcer formation, and stress-induced increases in dopaminergic activity in the prefrontal cortex have been shown to be associated with behavioral coping responses. These and other data have been interpreted as indicating that stress-induced increases in dopaminergic activity are important components of coping responses to environmental stressors rather than being a reflection of anxiety.

Yet, in trying to understand the functional significance of the activation of brain DA systems, it must be kept in mind that DA neurotransmission can be increased by a variety of environmental and behavioral challenges that are nonaversive. Such challenges include feeding, sexual activity, and exposure to drugs of abuse. Indeed, the dopaminergic pathway from the VTA to the NAC is critical for the reinforcing effects of many addictive drugs, including cocaine, morphine, and nicotine, as well as direct brain stimulation. These two seemingly contradictory observations – DA release is increased by stress and by positively reinforcing stimuli – can be reconciled if one assumes that any stimulus that causes behavioral arousal leads to an increase in DA neurotransmission. DA activation is probably essential for attention and survival. However, at some point the amount of activation becomes detrimental. For example, a rat trained to lever press in order to receive injections of cocaine will respond at a very steady rate. Such an animal will exhibit elevated rates of DA release in the NAC and other brain regions. If the dose of cocaine per injection is suddenly increased, however, the animal will reduce its rate of lever pressing such

that only enough cocaine is present to maintain the previous level of DA release. In other words, if given the choice, the animal will not allow the extent of DA activation to exceed some optimal level. It is likely that this optimum varies both from individual to individual and from physiological state to state. A similar inverted-U relationship between stress-induced DA activation and working memory has been well documented within the frontal cortex (Figure 3).

Responses of Dopaminergic Systems to Chronic Stress

Animals are often confronted with repeated or prolonged exposure to stressors, and this can lead to

additional neurobiological and behavioral changes. Under certain conditions, habituation can result – the animals cease responding to the stimulus. But under other conditions sensitization can occur. In this case, the animal's biological and/or behavioral responses increase to the next presentation of the same stimulus or to a different stimulus. Whether or not a given paradigm leads to habituation or sensitization is likely determined by the exact nature and duration of the stressors used, the species, and/or the brain region examined. These processes likely contribute to stress-related disorders such as anxiety, depression, and fibromyalgia.

Chronic stress can also lead to cross-sensitization to drugs of abuse such as cocaine, amphetamine, and opiates at both the behavioral and cellular level.

Figure 3 The inverted-U model for dopaminergic regulation of prefrontal function, which was originally proposed by Patricia Goldman-Rakic and colleagues. Top: A generalized model for DA function is depicted that assumes that, under normal conditions, there is a range of DA concentration over which signal processing in prefrontal neurons operates efficiently and working memory performance is sufficient to the task. At the center of this range is an optimum for cortical DA level, and D1 receptor stimulation in particular, at which performance is maximal. The exact shape and slope of this curve is likely task specific, such that complex tasks may be more sensitive to a narrower range of DA concentrations. Bottom: The curve may be altered in shape or slope (blue and yellow gradients) or be shifted to the left or right (green and brown gradients, respectively) depending on genotype, life history, and/or conditions. Individuals who suffer from deficiency of prefrontal DA transmission may benefit from DA receptor stimulation by agonists, whereas those who suffer from excessive endogenous transmission may benefit from treatment with DA receptor antagonists.

It is possible that sensitization plays a role in the development of posttraumatic stress disorder, panic attacks, and psychosis. Furthermore, because DA can oxidize to form potentially toxic metabolites, it has been hypothesized that the prolonged elevations in DA observed with repeated stress may lead to impairments of cellular functioning, although this possibility has not yet been rigorously examined.

Many cellular and molecular changes have been described in the development of neurochemical and behavioral sensitization following chronic stress. For example, chronic intermittent or sustained stress has been shown to induce changes in the number of DA receptors in several brain regions, including the prefrontal cortex and NAC. Chronic stress also leads to changes in TH expression in the VTA and in the activity of several components of DA receptor signaling in the NAC, dorsal striatum, and amygdala.

Interactions between Dopamine and other Neurochemical Systems Altered by Stress

Dopamine and the HPA Axis

Many neurochemical and hormonal systems are activated by stress. One of the best-characterized physiological responses to stress is the activation of the hypothalamic-pituitary-adrenocortical (HPA) axis. The HPA system controls secretion of glucocorticoids by the adrenal gland. Interestingly, several dopaminergic regions in the brain express glucocorticoid receptors, and the density of the receptors in these regions parallels the ability of stress to increase the activity of DA neurons: receptor density is higher in VTA than SN. There is reason to believe that the correlation between glucocorticoid receptors and stress-induced changes in DA release has functional significance. Administration of glucocorticoids can increase extracellular DA. Moreover, the suppression of stress-induced corticosterone secretion causes a reduction in the dopaminergic response to stress.

Glucocorticoid regulation of midbrain DA neurons also appears to be a biological substrate of the effects of stress on the propensity to develop drug abuse. Conversely, midbrain DA neurons also seem capable of regulating the HPA axis since loss of DA decreases the basal and stress-induced secretion of corticosterone.

Dopamine and Excitatory Amino Acids

Stress has been shown to increase the release of glutamate and other excitatory amino acids in many brain regions, including the prefrontal cortex, striatum, NAC, VTA, and hippocampus. The presence of glucocorticoids appears to be necessary for this response,

as adrenalectomy abolishes the stress-induced increase of extracellular glutamate, and corticosterone replacement restores this response. Glutamatergic neurons in the cortex project to the striatum and NAC as well as SN and VTA. Furthermore, glutamate agonists appear to increase the synthesis and release of DA in each of these regions, and it has been hypothesized that stress-induced activation of glutamate may contribute to stress-induced increases in DA. The local administration of glutamate antagonists into the region of the midbrain containing DA cell bodies can block stress-induced increases in extracellular DA in the striatum. Additionally, stress-induced increases in DA synthesis can be blocked by local administration of a glutamate antagonist directly into the striatum itself. Glutamate antagonists can also block stress-induced increases in extracellular DA in the prefrontal cortex. Intracellularly, glutamatergic and dopaminergic signals can converge on a single protein, the dopamine- and cAMP-regulated phosphoprotein (DARPP-32), a protein whose activation is a crucial component of neural signaling responses.

Dopamine and Norepinephrine

NE is formed from DA and shares many of its basic characteristics. Acute exposure to stress causes an activation of NE neurons in the locus coeruleus and an increase in both the synthesis and release of NE. The exact relationship between these events and stress-induced changes in DA is unclear. NE terminals in the prefrontal cortex can modulate the dopaminergic responses to stress. The NAC and striatum, on the other hand, exhibit increases in dopaminergic activity with stress but are NE-poor regions; presumably NE-DA interactions have little significance in these regions. However, novel roles for the NE-rich bed nucleus of the stria terminalis in mediating polysynaptic responses to stress and drugs of abuse have recently been implicated and are a current area of intense scrutiny.

Dopamine and Serotonin

The involvement of 5-HT in animal models of stress and depression has received great attention due to the antidepressant effects of selective 5-HT reuptake inhibitors (SSRIs) such as fluoxetine (Prozac). Acute exposure to stress leads to dramatic increases in 5-HT release in the striatum and other brain regions. Local administration of 5-HT agonists into the striatum can increase DA release, suggesting that it is possible that stress-induced increases in DA release are at least partially mediated by increases in 5-HT. Anatomical and electrophysiological evidence also suggests prominent interactions between 5-HT and DA in both cell body

and terminal regions. These effects appear to be mediated via multiple families of 5-HT receptors, including the 5-HT_{1A}, 5-HT_{2C}, and 5-HT₄ subtypes.

Dopamine and Dopamine

In developing an understanding of the role of DA neurotransmission in stress, one must take into consideration the functional differences among distinct brain DA systems. In particular, it must be remembered that mesocortical DA neurons inhibit glutamatergic cortical pyramidal neurons, which in turn can stimulate dopaminergic activity in nigrostriatal and mesoaccumbens neurons. Therefore, the less pronounced effects of acute stress on subcortical DA systems may be due in part to the suppression of subcortical DA systems by activated mesocortical DA neurons. Consistent with this hypothesis, depletion of DA in the prefrontal cortex enhances the stress-induced increase in dopaminergic transmission in the NAC_{shell}. Furthermore, injection of a DA receptor antagonist into the prefrontal cortex has been shown to block the DA stress response in the NAC. Last, under certain conditions, chronic stress produces neurochemical tolerance in the prefrontal cortex but sensitization in subcortical areas.

Interactions between cortical and subcortical DA systems have also been proposed in the pathophysiology of schizophrenia. A dysfunction of dopaminergic signaling in the prefrontal cortex can produce secondary disruptions in subcortical DA systems and vice versa. In fact, decreases in the expression of TH and DA receptors in the prefrontal cortex have recently been described. The effects of cortical DA depletion on subcortical DA stress responses may thus be of particular clinical importance given that stress is known to exacerbate psychotic symptoms in schizophrenic patients.

Developmental Modulation

Finally, recent studies have demonstrated major effects of altering neurodevelopmental trajectory on subsequent functioning of brain DA systems. For example, prenatal exposure to stress or drugs of abuse can permanently alter the anatomical organization and cellular responses of both midbrain DA neurons and their forebrain targets. The quality of parental care has also been observed to alter these relationships in both animal models and humans. For example, repeated periods of maternal separation during early life decreases DA transporter expression and increases behavioral and brain DA responses to stress. DA systems are also uniquely sensitive to environmental, genetic, and/or pharmacological modifications

during adolescence. Responses of brain DA systems to stress, therefore, are critically impacted by genetic and environmental risk factors. Elucidation of these risk factors, their specific effects on brain maturation, and the development of therapeutic methods to normalize developmental trajectory in their presence are all important areas of active research.
